PROCEEDINGS

OF THE

ROYAL SOCIETY OF MEDICINE

EDITED UNDER THE DIRECTION OF THE EDITORIAL COMMITTEE

HONORARY EDITORS: E. C. WARNER, M.D., F.R.C.P., AND SELWYN TAYLOR, M.CH., F.R.C.S.

EDITOR: J. M. BROWNE KUTSCHBACH, M.B., D.P.H.

VOLUME THE FIFTIETH *JANUARY TO DECEMBER 1957*

(SESSION OCTOBER 1956—SEPTEMBER 1957)

SECTIONS

ANÆSTHETICS
CLINICAL
COMPARATIVE MEDICINE
DERMATOLOGY
ENDOCRINOLOGY
EPIDEMIOLOGY AND PREVENTIVE MEDICINE
EXPERIMENTAL MEDICINE AND THERAPEUTICS
GENERAL PRACTICE
HISTORY OF MEDICINE
LARYNGOLOGY
MEDICINE
NEUROLOGY
OBSTETRICS AND GYNÆCOLOGY
ODONTOLOGY
OPHTHALMOLOGY
ORTHOPÆDICS
OTOLOGY
PÆDIATRICS
PATHOLOGY
PHYSICAL MEDICINE
PROCTOLOGY
PSYCHIATRY
RADIOLOGY
SURGERY
UNITED SERVICES
UROLOGY

1957

CONTENTS OF SECTIONS

PROCEEDINGS VOLUME 50, 1957

	PAGE Sect.	Vol.
The Royal Society of Medicine		
Golden Jubilee Number		
October No.		
FOREWORD. By Sir Francis Walshe, O.B.E., M.D., F.R.S.	—	722
PORTRAIT OF SIR WILLIAM SELBY CHURCH .. .. .. *facing*	—	722
PORTRAIT OF SIR CLEMENT PRICE THOMAS .. .. .. *facing*	—	723
INTRODUCTION. By E. C. Warner, M.D., F.R.C.P., and Selwyn Taylor, M.Ch., F.R.C.S., Honorary Editors	—	723
Sherrington Memorial Lecture		
December No. Meeting Nov. 27, 1957		
THE ANALYSIS OF THE NERVOUS SYSTEM. By The Right Hon. Lord Adrian, O.M., F.R.S., M.D., F.R.C.P.	—	991
Book Reviews		
January No.	—	49
February No.	—	113
March No.	—	207
June No.	—	423
July No.	—	527
August No.	—	621
September No.	—	703
October No.	—	893
November No.	—	977
December No.	—	1065
Section of Anæsthetics		
January No. Meeting Nov. 2, 1956		
THE ANÆSTHETIST'S ROLE IN UNDERGRADUATE TRAINING [*Abridged*]. President's Address by Katharine G. Lloyd-Williams, C.B.E., M.D. F.F.A. R.C.S.	1	13
February No. Meeting Oct. 5, 1956		
ELECTROENCEPHALOGRAPHY in RELATION TO ANÆSTHESIA [*Abridged*]. Registrars' Prize Essay by Sheila M. Wilson, M.B., F.F.A. R.C.S., D.A.	5	105
THE ROLE OF POSTURE IN LAMINECTOMY [*Abridged*]. Registrars' Prize Essay by D. J. Pearce, M.B., F.F.A. R.C.S., D.A.	9	109
March No. Meeting Dec. 7, 1956		
FLUOROMAR IN ANÆSTHESIA. By John W. Dundee, M.D., F.F.A. R.C.S.	13	191
SOME OBSERVATIONS ON FLUOTHANE. By R. Bryce-Smith, D.M., F.F.A. R.C.S., and H. D. O'Brien, M.B., F.F.A. R.A.C.S.	15	193
August No. Meeting Jan. 4, 1957		
DISCUSSION ON ANÆSTHESIA FOR OBSTETRICS: AN EVALUATION OF GENERAL AND REGIONAL METHODS [*Abridged*]	21	547
Dr. O. P. Dinnick	21	547
Mr. J. S. Tomkinson	26	552
Dr. G. C. Steel	27	553
Dr. J. M. Holmes, Dr. C. J. Massey Dawkins, Dr. H. R. Youngman	30	556
October No. Meeting Feb. 1, 1957		
RESUSCITATION OF THE BURNED CHILD. By D. W. Shannon, M.B., Ch.B., F.F.A. R.C.S., D.A.	31	885
ANÆSTHESIA FOR BURNED CHILDREN. By Harry Middleton, F.F.A. R.C.S.	34	888
November No. Meeting April 5, 1957		
PROBLEMS OF ANÆSTHESIA IN RELATION TO CARDIOVASCULAR SURGERY. By Ole Secher, M.D.	39	983
Clinical Section		
February No. Meeting Nov. 9, 1956		
THE SOLUTION OF A SURGICAL DILEMMA. By Geoffrey Flavell, F.R.C.S., M.R.C.P.	1	115
List of other Cases shown	3	117
February No. Meeting Dec. 14, 1956		
List of Cases shown	3	117
June No. Meeting Feb. 8, 1957		
PNEUMONECTOMY FOR AGENETIC LUNG. By M. C. Waterfall, F.R.C.S. ..	5	401
WALDENSTRÖM'S SYNDROME OR MACROGLOBULINÆMIA. By D. W. Oxbrow, M.B., B.S. (for S. Karani, M.B., B.S., M.R.C.P.)	6	402
RENAL FAILURE TREATED WITH PREDNISOLONE. By J. E. Lennard-Jones, M.B., M.R.C.P. (for Richard Asher, M.D., F.R.C.P.)	7	403
List of other Cases shown	8	404
July No. Meeting March 8, 1957		
Meeting Held at the Whittington Hospital, London		
INTRAHEPATIC PORTAL HYPERTENSION DUE TO MUCOVISCIDOSIS. By T. St. M. Norris, M.D., M.R.C.P., D.P.H.	9	507
MYELOPROLIFERATIVE SYNDROME PRESENTING AS "NEUTROPHILIC LEUKÆMIA". By A. N. Exton-Smith, M.D., M.R.C.P. (with the assistance of A. A. Chazan, M.B.)	12	510
BILATERAL URETERO-SIGMOIDOSTOMY, ACIDOSIS, OSTEOMALACIA. By Arnold Bloom, M.D., M.R.C.P..	14	512

	PAGE Sect.	Vol.
CERVICAL PAIN AS A SYMPTOM OF HYPOTENSION DURING TREATMENT WITH GANGLIO-PLEGIC DRUGS. By E. Montuschi, M.D., M.R.C.P. ..	16	514
IDIOPATHIC HYPERCATABOLIC HYPOPROTEINÆMIA. By W. R. Cattell, M.B., M.R.C.P. (for T. St. M. Norris, M.D., M.R.C.P., D.C.H.)	16	514
List of other Cases and Demonstrations	18	516
October No. Meeting March 8, 1957, *contd.*		
Meeting Held at the Whittington Hospital, London		
SPONTANEOUS GASTRO-JEJUNOSTOMY. By W. W. Davey, M.D., F.R.C.S., F.R.C.S.I.	19	881
HEPATO-LENTICULAR DEGENERATION. By Michael Ashby, B.M., M.R.C.P.	22	884
November No. Meeting May 10, 1957		
Meeting at the Royal Berkshire Hospital, Reading		
CARDIOSPASM AND EPITHELIOMA OF ŒSOPHAGUS TREATED BY ŒSOPHAGECTOMY. By G. L. Bohn, F.R.C.S.	23	923
HYPERTENSION DUE TO UNILATERAL RENAL LESION. By C. Latto, F.R.C.S.	23	923
DEXTRO-INVERSIO CORDIS. By Alastair Anderson, F.R.C.P.	24	924
MULTIPLE KIDNEY OPERATIONS FOR CYSTINE CALCULI. By G. L. Bohn, F.R.C.S.	25	925
TWO CASES OF CARCINOMA OF THE AMPULLA OF VATER TREATED BY LOCAL EXCISION. By R. G. Reid, F.R.C.S.	25	925
List of other Cases shown	26	926

Section of Comparative Medicine

	PAGE Sect.	Vol.
April No. Meeting Dec. 19, 1956		
DISCUSSION ON TUBERCULIN SENSITIVITY	1	253
Dr. A. B. Paterson	1	253
Dr. T. Francis Jarman	3	255
August No. Meeting March 20, 1957		
DISCUSSION ON MAMMARY TUMOURS	9	557
Mr. E. Cotchin	9	557
Professor Geoffrey Hadfield ..	12	560
Mr. W. P. Greening	13	561
Dr. I. Lewin	15	563
September No. Meeting April 17, 1957		
DISCUSSION ON ARTIFICIAL INSEMINATION	23	683
Dr. Margaret Hadley Jackson ..	23	683
Mr. Reynold Boyd	25	685
October No. Meeting May 15, 1957		
DISCUSSION: RECENT ADVANCES IN THE USE OF TISSUE CULTURE METHODS IN VIRUS RESEARCH ..	29	911
Dr. F. Kingsley Sanders	29	911
Mr. R. F. Sellers	33	915
Mr. T. W. F. Pay	37	919

Section of Dermatology

	PAGE Sect.	Vol.
January No. Meeting Oct. 18, 1956		
LEG ULCER AND RHEUMATOID ARTHRITIS. THREE CASES. By F. Ray Bettley, F.R.C.P.	1	17
ELEPHANTIASIS NOSTRAS. By Brian Russell, F.R.C.P.	2	18
STILL'S DISEASE WITH RECURRENT ULCERATION OF THE LEGS. By C. M. Ridley, M.R.C.P. (for Brian Russell, F.R.C.P.)	3	19
List of other Cases shown	3	19
April No. Meeting Nov. 15, 1956		
TUBERCULOUS GLANDS WITH SKIN INVOLVEMENT. By S. P. Hall-Smith, M.D., M.R.C.P., and J. McMurray, M.D.	5	275
ACANTHOSIS NIGRICANS. By P. J. Hare, M.D., M.R.C.P.	6	276
NECROBIOSIS LIPOIDICA. By P. J. Hare, M.D., M.R.C.P.	7	277
List of other Cases shown	7	277
April No. Meeting Dec. 20, 1956		
MELANOSIS. By D. I. Williams, F.R.C.P.	7	277
TUBERCULOID LEPROSY. By E. N. M. Johnston, M.B., M.R.C.P. (for H. J. Wallace, M.D., F.R.C.P.) ..	8	278
DIMORPHOUS LEPROSY. By E. N. M. Johnston, M.B., M.R.C.P. (for H. J. Wallace, M.D., F.R.C.P.) ..	8	278
ATROPHIE BLANCHE. By R. H. Marten, B.M., M.R.C.P. (for Sydney Thomson, M.D., F.R.C.P.)	9	279
List of other Cases shown	9	279
June No. Meeting Jan. 17, 1957		
PRESENTATION OF DIPLOMA OF HONORARY MEMBERSHIP OF THE SECTION TO SIR ARCHIBALD GRAY	11	391
SARCOIDOSIS WITH SKIN LESIONS SIMULATING NECROBIOSIS LIPOIDICA. By P. F. Borrie, M.R.C.P. ..	11	391
IMPETIGO HERPETIFORMIS. By M. Feiwel, M.R.C.P., and D. Ferriman, D.M., M.R.C.P.	12	392
List of other Cases shown	14	394
July No. Meeting Feb. 21, 1957		
STILL'S DISEASE WITH PSEUDOXANTHOMA ELASTICUM. By Stephen C. Gold, M.D.	15	473

	PAGE Sect.	Vol.
XERODERMA PIGMENTOSUM. By Stephen C. Gold, M.D.	16	474
XERODERMA PIGMENTOSUM. By B. Schwartz, M.D. (for Hugh Gordon, M.C., F.R.C.P.)	16	474
DERMATOMYOSITIS. By B. Schwartz, M.D.	18	476
List of other Cases shown	18	476
August No. Meeting March 21, 1957		
DERMABRASION. By J. S. Pegum, M.D., M.R.C.P.	19	607
DERMABRASION. By Patrick Clarkson, M.B.E., F.R.C.S.	20	608
TUBERCULIDES. By O. L. S. Scott, M.R.C.P.	21	609
DERMAL LEISHMANIASIS. By R. G. Howell, M.R.C.P.	21	609
SARCOIDOSIS WITH AN UNUSUAL ARTHRITIS. By C. M. Ridley, B.M., M.R.C.P. (for J. S. Pegum, M.D., M.R.C.P.)	21	609
October No. Meeting April 25, 1957		
PARAPSORIASIS. By J. T. Ingram, M.D.	23	771
PARAPSORIASIS LICHENOIDES EN PLAQUE, WITH NECROTIC NODULES, SHOWING FEATURES OF POIKILODERMA. By L. Forman, M.D., F.R.C.P.	25	773
November No. Meeting March 21, 1957, *contd.*		
List of other Cases shown	27	931
November No. Meeting April 25, 1957, *contd.*		
HISTIOCYTIC RETICULOSIS. By Geoffrey Hodgson, M.B.E., M.D.	27	931
THREE CASES OF PARAPSORIASIS EN PLAQUES. By Brian F. Russell, M.D., F.R.C.P.	28	932
PSORIASIS AND MYCOSIS FUNGOIDES. By K. M. Harvey, M.B. (for Brian F. Russell, M.D., F.R.C.P.) ..	29	933
MYCOSIS FUNGOIDES DEVELOPING ON PARAPSORIASIS EN PLAQUES. By Brian Potter, M.D. (for Brian F. Russell, M.D., F.R.C.P.)	30	934
POIKILODERMIA (JACOBI-LANE). By J. S. Pegum, M.R.C.P.	31	935
POIKILODERMIA DEVELOPING MYCOSIS FUNGOIDES. By E. N. M. Johnston, M.R.C.P.	31	935
MYCOSIS FUNGOIDES TREATED WITH PREDNISONE. By L. Forman, M.D., F.R.C.P.	32	936
December No. Meeting May 16, 1957		
PAPULONECROTIC TUBERCULIDES WITH MILIARY TUBERCULOSIS. By I. S. Hodgson-Jones, M.D., M.R.C.P.	33	1019
INCONTINENTIA PIGMENTI. By W. Frain-Bell, M.D., M.R.C.P.Ed. (for R. T. Brain, M.D.)	33	1019
NECROBIOSIS LIPOIDICA DIABETICORUM AND GRANULOMA ANNULARE. By W. Frain-Bell, M.D., M.R.C.P.Ed.	34	1020
List of other Cases shown	34	1020
December No. Meeting June 20, 1957		
MACULAR ATROPHY OF THE SKIN. By R. G. Howell, M.R.C.P.	35	1021
EHLERS-DANLOS SYNDROME. By E. Wilson Jones, M.R.C.P. (for H. J. Wallace, F.R.C.P.)	35	1021
EHLERS-DANLOS SYNDROME, WITH SPONDYLOLISTHESIS AND MALFORMATION OF THE TERMINAL DIGITS. By Louis Forman, M.D., F.R.C.P.	36	1022
List of other Cases shown	36	1022

Section of Endocrinology

	PAGE Sect.	Vol.
January No. Meeting Oct. 24, 1956		
DIAGNOSTIC PROCEDURES IN BONE DISEASE [*Abridged*]. President's Address by T. Russell Fraser, M.D., F.R.C.P., D.P.M.	1	21
June No. Meeting Jan. 23, 1957		
DISCUSSION ON AMENORRHŒA AND HIRSUTISM	5	453
Dr. J. H. Rey	5	453
Dr. B. T. Donovan	7	455
Dr. P. Kynaston Thomas and Dr. David Ferriman	9	457
Dr. P. M. F. Bishop and Mr. R. D. de Vere	10	458
Dr. Raymond Greene	12	460
June No. Meeting Feb. 27, 1957		
List of Speakers	12	460
June No. Meeting March 20, 1957 Joint Meeting with Society for Endocrinology		
List of Papers presented	12	460
October No. Meeting Nov. 28, 1956		
DISCUSSION ON CUSHING'S SYNDROME	13	761
Dr. R. I. S. Bayliss	13	761
Dr. Richard Asher	16	764
Dr. A. Stuart Mason	18	766
Dr. J. D. N. Nabarro, Dr. C. L. Cope, Dr. A. W. Spence ..	20	768
Dr. A. C. Crooke, Mr. R. B. Welbourn	21	769
Dr. Leonard Simpson, Dr. O. Garrod	22	770
November No. Meeting May 22, 1957		
DISCUSSION ON HASHIMOTO'S DISEASE	23	943
Dr. R. W. Luxton	23	943
Dr. Deborah Doniach, Mr. R. Vaughan Hudson and Dr. I. M. Roitt	26	946
Dr. A. D. Thomson	30	950

	PAGE Sect.	Vol.
Section of Epidemiology and Preventive Medicine		
January No. Meeting Oct. 19, 1956		
THE CHANGING EPIDEMIOLOGY OF SONNE DYSENTERY [*Abridged*]. President's Address by Ian Taylor, M.D., M.R.C.P., D.P.H.	1	31
April No. Meeting Nov. 16, 1956		
DISCUSSION ON THE EPIDEMIOLOGY OF CANCER	7	249
Dr. J. Knowelden	7	249
Dr. Alice Stewart	9	251
December No. Meeting May 31, 1957		
DISCUSSION ON POLIOMYELITIS VACCINATION IN 1956	11	1067
Professor C. H. Stuart-Harris ..	11	1067
Dr. W. Wood	12	1068
Dr. J. O'H. Tobin	14	1070
Dr. J. Knowelden	16	1072
Section of Pathology with Section of Epidemiology and Preventive Medicine		
(*JOINT MEETING No.* 5)		
October No. Meeting Jan. 15, 1957		
DISCUSSION ON ADENOVIRUS INFECTIONS	—	753
Dr. B. E. Andrews and Dr. J. C. McDonald	—	753
Dr. H. G. Pereira and Barbara Kelly	—	755
Dr. R. G. Sommerville	—	757
Dr. P. K. Hopper, Dr. C. H. Smith, Mr. Barrie R. Jones ..	—	758
Major R. J. C. Hart	—	760
Section of Experimental Medicine and Therapeutics		
January No. Meeting May 7, 1956		
SYMPOSIUM ON ANTI-TUMOUR AGENTS	1	1
Dr. Walter Davis	1	1
Dr. A. L. Walpole	4	4
Professor J. F. Danielli, Dr. Edith Paterson	5	5
Dr. George Bosworth Brown, Dr. Aaron Bendich	6	6
Dr. Gertrude B. Elion	7	7
Mr. G. M. Timmis..	8	8
Dr. D. A. G. Galton	10	10
Dr. F. G. J. Hayhoe, Dr. R. L. Worrall	12	12
February No. Meeting Oct. 9, 1956		
DISCUSSION ON HYPOTHERMIA ..	13	75
Dr. E. Neil	13	75
Dr. B. G. B. Lucas, Mr. D. N. Ross	14	76
Dr. H. H. Khalil	16	78
July No. Meeting Feb. 12, 1957		
CHEMICAL CAUSES OF PAIN AND ITCH. President's Address by Professor C. A. Keele, M.D., F.R.C.P. ..	17	477
October No. Meeting Dec. 11, 1956		
Walter Ernest Dixon Memorial Lecture [Number 8]		
ION MOVEMENT AND CARDIAC FIBRILLATION. By J. Harold Burn, M.D., F.R.S.	25	725
November No. Meeting May 8, 1957		
DISCUSSION ON AUTO-IMMUNITY AND THYROIDITIS	37	953
Dr. R. G. White	37	953
Professor Ernest Witebsky ..	39	955
Dr. I. M. Roitt and Dr. Deborah Doniach	42	958
Dr. W. R. Trotter, Dr. G. Belyavin and Dr. A. Waddams	45	961
November No. Meeting June 7, 1957		
DISCUSSION ON THE PENETRATION OF DRUGS INTO THE CEREBROSPINAL FLUID	47	963
Dr. Hugh Davson	47	963
Dr. Honor V. Smith	48	964
Section of General Practice		
January No. Meeting Oct. 17, 1956		
PÆDIATRICS IN GENERAL PRACTICE. Valedictory Address by Geoffrey Barber, O.B.E., M.A., M.B. ..	1	25
March No. Meeting Nov. 21, 1956		
DISCUSSION ON CATARRH AND ITS TREATMENT	7	167
Dr. Harold Bloom	7	167
Dr. Guy Daynes	10	170
Dr. H. C. Faulkner	11	171
June No. Meeting Dec. 19, 1956		
DISCUSSION ON THE AFTERMATH OF HYSTERECTOMY AND OOPHORECTOMY	13	415
Dr. Katharina Dalton	13	415
Dr. G. J. V. Crosby	16	418
Mr. John Beattie	18	420
Mr. Aleck Bourne	19	421
Professor W. C. W. Nixon, Mr. Frank Musgrove, Dr. E. Robert Rees, Dr. A. R. L. Abel ..	20	422
July No. Meeting Feb. 20, 1957		
DISCUSSION ON THE MODERN OUTLOOK IN THE MANAGEMENT OF PULMONARY TUBERCULOSIS ..	21	485
Dr. K. Neville Irvine	21	485
Sir Geoffrey Marshall	24	488
Sir Clement Price Thomas ..	25	489

	PAGE Sect.	Vol.
August No. Meeting April 17, 1957		
DISCUSSION: EYES IN GENERAL PRACTICE	29	577
Dr. John Fry	29	577
Mr. Joseph Minton	30	578
Mr. F. A. Williamson-Noble	31	579
Mr. J. P. F. Lloyd	32	580
October No. Meeting March 20, 1957		
DISCUSSION ON COMMON CONGENITAL ABNORMALITIES AND THEIR MANAGEMENT IN GENERAL PRACTICE	33	809
Dr. Lindsey W. Batten	33	809
Dr. G. B. Mitchell-Heggs	35	811
Mr. D. N. Matthews	38	814

Section of Otology with Section of General Practice

(*JOINT MEETING No.* 2)

June No. Meeting Feb. 1, 1957		
DISCUSSION ON RECURRENT OTITIS MEDIA IN CHILDREN	—	405
Mr. Lionel Taylor	—	405
Dr. I. Friedmann	—	406
Dr. G. F. Abercrombie	—	409
Dr. David Wheatley	—	410
Mr. S. R. Mawson, Mr. A. G. Tresidder, Dr. L. Roodyn	—	412
Mr. S. W. Allinson, Dr. G. O. Barber, The Chairman, Mr. F. C. W. Capps, Mr. G. H. Bateman, Mr. J. F. Lipscomb, Dr. R. Goulding	—	413
Dr. L. W. Batten, Mr. J. W. S. Lindahl, Mr. Lionel Taylor, Dr. D. Wheatley, The Chairman	—	414

Section of the History of Medicine

March No. Meeting Dec. 5, 1956		
THE HISTORY OF ST. PETER'S HOSPITAL FOR STONE, LONDON. By Cuthbert E. Dukes, M.D., F.R.C.S.	1	161
THE HISTORY OF ST. PAUL'S HOSPITAL, LONDON. By A. R. C. Higham, F.R.C.S.	4	164
April No. Meeting Nov. 7, 1956		
MEDICINE AND DENTISTRY IN NEWCASTLE UPON TYNE IN THE EIGHTEENTH CENTURY. By John Boyes, F.R.C.S.Ed.	7	229
April No. Meeting Feb. 6, 1957		
WHITHER MEDICAL HISTORY? [*Abstract*]. President's Address by Douglas Guthrie, M.D., F.R.C.S.Ed., F.R.S.Ed.	14	236
August No. Meeting May 1, 1957		
THE PATTERN OF AUSTRALIAN MEDICAL HISTORY. By Brian Gandevia, M.D., M.R.A.C.P.	15	591
December No. Meeting March 6, 1957		
INTRODUCTION TO WESTERN INFLUENCES IN PRE-MEIJI JAPANESE MEDICINE. By Gordon E. Mestler	23	1005
December No. Meeting April 3, 1957		
WORMS IN HISTORY WITH SPECIAL REFERENCE TO CHILDREN. By John Rendle-Short, M.D., M.R.C.P., D.C.H.	31	1013

Section of Laryngology

June No. Meeting Feb. 1, 1957		
DISCUSSION ON FACIAL AND PALATAL REPAIR IN THE TREATMENT OF MALIGNANT DISEASE	1	433
Mr. W. A. Mill	1	433
Mr. R. J. V. Battle	3	435
Mr. J. H. Hovell	7	439
The President, Mr. E. Musgrave Woodman	9	441
Mr. Mill, Mr. Battle	10	442
June No. Meeting Dec. 7, 1956		
Discussion (*By Title*) and List of Clinical Records presented	10	442
June No. Meeting March 1, 1957		
Discussion and Papers (*By Title*)	10	442
October No. Meeting Nov. 2, 1956		
A LARYNGOLOGIST'S VIEW ON ALLERGY. President's Address by J. Angell James, M.D., M.R.C.P., F.R.C.S.	11	827
December No. Meeting May 3, 1957		
DISCUSSION ON TUBERCULOUS CERVICAL ADENITIS	21	1057
Mr. T. J. Wilmot	21	1057
Mr. J. J. Mason Brown	24	1060
Dr. E. F. James	27	1063

(For Joint Summer Meeting, June 27–29, 1957, *see September No.*, p. 702)

Section of Medicine

January No. Meeting Oct. 23, 1956		
MALIGNANT CARCINOID TUMOURS. By Reginald E. B. Hudson, M.D.	1	37
MALIGNANT CARCINOID TUMOURS. By R. S. Stacey, M.A., M.D.	4	40
ENDOMYOCARDIAL FIBROSIS. By J. Donald Ball, M.R.C.P.	7	43
PRIMARY AMYLOIDOSIS. By R. I. S. Bayliss, M.A., M.D., F.R.C.P.	11	47

	PAGE Sect.	Vol.
May No. Meeting Nov. 27, 1956		
DISCUSSION ON THE MANAGEMENT OF PATIENTS SUFFERING FROM PULMONARY TUBERCULOSIS	13	335
Dr. A. Brian Taylor	13	335
Mr. W. P. Cleland	14	336
Dr. Peter Stradling	20	342
July No. Meeting Jan. 22, 1957		
DISCUSSION ON ANURIA IN MEDICAL CONDITIONS	25	493
Dr. M. D. Milne	25	493
Dr. A. M. Joekes	28	496
Dr. E. M. Darmady	30	498
July No. Meeting Feb. 26, 1957		
DISCUSSION ON THE PHARMACOLOGICAL AND MEDICAL ASPECTS OF SMOKING	32	500
Professor J. H. Burn	32	500
Dr. Richard Doll	35	503
Dr. Neville Oswald	36	504
September No. Meeting March 26, 1957		
DISCUSSION ON DIAGNOSTIC FEATURES OF SOME PANCREATIC DISEASES ..	39	639
Dr. T. C. Hunt	39	639
Mr. Rodney Smith	40	640
Dr. Martin Bodian	41	641
September No. Meeting May 28, 1957		
DISCUSSION ON SOME BLOOD DISORDERS	44	644
HYPERSPLENISM. By M. C. G. Israëls, M.D., F.R.C.P. ..	44	644
RECENT ADVANCES IN THE DIAGNOSIS AND TREATMENT OF HÆMOPHILIA. By Rosemary Biggs, M.D.	45	645
THE COLD HÆMAGGLUTININ SYNDROME. By J. V. Dacie, M.D., F.R.C.P.	47	647
October No. Meeting April 30, 1957		
DISCUSSION ON AORTIC STENOSIS ..	51	817
Dr. Raymond Daley	51	817
Mr. Andrew Logan	54	820
Dr. J. F. Goodwin	57	823
Mr. W. P. Cleland	58	824
Dr. Ronald Gibson, Mr. Ian M. Hill, Mr. D. N. Ross	59	825
Mr. B. B. Milstein, Dr. C. J. Gavey, Mr. I. K. R. McMillan	60	826

Section of Neurology

	PAGE Sect.	Vol.
April No. Meeting Nov. 1, 1956		
Meeting at the National Hospital for Nervous Diseases, Queen Square, London		
List of Cases shown	1	281
April No. Meeting Dec. 6, 1956		
DISCUSSION ON THE EARLY MANAGEMENT OF SUBARACHNOID HÆMORRHAGE	1	281
Dr. J. MacDonald Holmes ..	1	281
Dr. R. A. Henson	4	284
Mr. J. M. Small	9	289
May No. Meeting Jan. 3, 1957		
THE AMYOTONIA CONGENITA SYNDROME. By John N. Walton, M.D., M.R.C.P.	11	301
THE HISTOCHEMISTRY OF NORMAL AND ABNORMAL HUMAN MUSCLE. By E. B. Beckett, B.Sc., and G. H. Bourne, D.Sc., D.Phil.	18	308
September No. Meeting March 7, 1957		
Meeting at the West End Hospital for Neurology and Neurosurgery, London		
List of Cases shown	23	661
September No. Meeting April 4, 1957		
DISCUSSION ON DISORDERS OF THE HIND-BRAIN CIRCULATION	23	661
Mr. John M. Potter	23	661
Dr. E. C. Hutchinson	24	662
Dr. P. O. Yates	25	663
October No. Meeting Feb. 7, 1957		
DISCUSSION ON THE CHANGING VALUES IN ELECTROENCEPHALOGRAPHY	29	899
Dr. Denis Hill	29	899
Dr. Gerald Parsons-Smith ..	35	905
Dr. J. A. V. Bates	38	908
Section of Neurology with Section of Psychiatry		
(*JOINT MEETING No.* 4)		
August No. Meeting May 2, 1957		
DISCUSSION ON THE TOXIC EFFECTS OF DRUGS USED IN NEUROLOGICAL AND PSYCHIATRIC PRACTICE ..	—	611
Dr. Hugh Garland	—	611
Dr. David Stafford-Clark	—	615
Dr. M. Weatherall	—	617

Section of Obstetrics and Gynæcology

	PAGE Sect.	Vol.
March No. Meeting Oct. 26, 1956		
SOME CLINICAL ASPECTS OF DEVELOPMENTAL ANOMALIES OF THE FEMALE GENITO-URINARY TRACT. President's Address by R. A. Brews, M.D., M.S., F.R.C.S., F.R.C.O.G. ..	1	199
March No. Meeting Jan. 25, 1957		
List of Cases and Specimens shown ..	8	206

	PAGE Sect.	Vol.
April No. Meeting Nov. 23, 1956		
DISCUSSION ON DYSMENORRHŒA AND UNEXPLAINED PELVIC PAIN ..	9	243
Mr. Wilfrid Mills	9	243
Mr. Wilfrid Mills, Mr. Albert Davis	11	245
Mr. G. W. Theobald	12	246
June No. Meeting March 22, 1957		
THE ÆTIOLOGY OF FIBROIDS. By Percy Malpas, F.R.C.S., F.R.C.O.G.	15	381
HABITUAL ABORTION. By V. B. Green-Armytage, M.D., F.R.C.P., F.R.C.S., F.R.C.O.G.	19	385
Film : TECHNIQUE OF WERTHEIM'S HYSTERECTOMY. By Mr. David Currie	20	386
June No. Meeting April 26, 1957		
List of Specimens shown	20	386
October No. Meeting Feb. 22, 1957		
DISCUSSION ON THE ÆTIOLOGY OF PRE-ECLAMPSIA	21	787
Professor J. C. McClure Browne ..	21	787
Mr. Norman Morris	22	788
Mr. John Sophian	24	790
October No. Meeting May 24, 1957		
DISCUSSION ON PREVENTION OF ECLAMPSIA	27	793
Professor G. Gordon Lennon ..	27	793
Mr. C. Keith Vartan	29	795
December No. Meeting June 28, 1957		
MEDICO-LEGAL ADVENTURES AND MISADVENTURES IN GYNÆCOLOGY AND OBSTETRICS [*Abridged*]. By F. E. Camps, M.D., D.T.M.&H. ..	33	1053

Section of Odontology

	PAGE Sect.	Vol.
March No. Meeting Nov. 26, 1956		
BASIC ASPECTS OF MOUTH DEVELOPMENT. By C. H. Tonge, T.D., M.B., B.S., B.D.S.	1	185
MARKED PAGET'S DISEASE, MAINLY OF THE MANDIBLE, IN A WOMAN. By Warren Harvey, M.R.C.S., L.R.C.P., F.D.S. R.C.S.Eng. ..	6	190
May No. Meeting Jan. 28, 1957		
MUSCLES AND THE TEETH. By W. J. Tulley, B.D.S., F.D.S. R.C.S., D.Orth.R.C.S.	7	313
September No. Meeting Feb. 25, 1957		
AN EXAMINATION OF DENTINE FOR A and B BLOOD-GROUP ANTIGENS BY THE MIXED AGGLUTINATION TECHNIQUE. By Ivor R. H. Kramer, M.D.S.Lond., L.D.S.Eng.	15	677
September No. Meeting Mar. 25, 1957		
CERVICO-FACIAL ACTINOMYCOSIS WITH ACUTE PRESENTATION. By H. P. Cook, M.B., B.S., B.D.S., F.D.S. (for B. St. J. Steadman, L.R.C.P., M.R.C.S., B.D.S.)	16	678
FRACTURE OF MANDIBLE. By John Cambrook, M.R.C.S., L.R.C.P., F.D.S.	16	678
EROSIVE LICHEN PLANUS OF THE MOUTH. By John Cambrook, M.R.C.S., L.R.C.P., F.D.S. ..	16	678
CHONDROSARCOMA OF THE MAXILLA AND SEPTUM. By George T. Hankey, O.B.E., T.D., F.D.S., M.R.C.S.	17	679
PRIMARY SQUAMOUS-CELL CARCINOMA OF MANDIBLE ARISING FROM EPITHELIAL LINING OF DENTAL CYST. By George T. Hankey, O.B.E., T.D., F.D.S., L.R.C.P., M.R.C.S., and J. A. Pedler, M.D.S., F.D.S., L.R.C.P., M.R.C.S.	18	680
September No. Meeting April 29, 1957		
ACUTE MONOCYTIC LEUKÆMIA. By H. P. Cook, M.B., B.S., B.D.S., F.D.S. R.C.S.	19	681
October No. Meeting Oct. 22, 1956		
A HUNDRED YEARS OF DENTISTRY. President's Address by J. A. S. Wright, A.F.C., F.D.S. R.C.S.Eng., H.D.D., F.D.S. R.C.S.Ed. ..	21	747

Section of Ophthalmology

	PAGE Sect.	Vol.
February No. Meeting Nov. 8, 1956		
DISCUSSION ON THE NEURO-OPHTHALMOLOGICAL ASPECTS OF THE CEREBRAL ANGIOMAS	1	85
Dr. Helen Dimsdale	1	85
Mr. H. E. Hobbs	5	89
Dr. David Sutton	7	91
The President, Mr. E. F. King ..	8	92
March No. Meeting Dec. 13, 1956		
DISCUSSION ON THE VISUAL PROBLEMS OF NIGHT DRIVING	9	173
Mr. L. H. Savin	9	173
Mr. H. C. Weston	12	176
Mr. G. Grime	15	179
September No. Meeting June 13, 1957		
DISCUSSION: TONOMETRY	21	667
Dr. J. Gloster	21	667
Mr. E. S. Perkins	24	670
Dr. C. R. S. Jackson	28	674
November No. Meeting May 9, 1957		
ARTERIOSCLEROTIC OPTIC ATROPHY. By Donald J. Lyle, M.D.	31	937

Section of Orthopædics

	PAGE Sect.	Vol.
April No. Meeting Nov. 6, 1956		
OSTEOID OSTEOMA OF THE TRANSVERSE PROCESS OF THE FIFTH CERVICAL VERTEBRA. By F. Godsalve Ward, F.R.C.S. ..	1	261
TWO CASES OF SARCOIDOSIS WITH PERIPHERAL JOINT MANIFESTATION. By R. A. Bremner, F.R.C.S. (for P. H. Newman, D.S.O., F.R.C.S.)	2	262
LIPOMA CAUSING A POSTERIOR INTEROSSEOUS NERVE LESION. By A. D. Thom, M.B. (for R. H. Maudsley, F.R.C.S.)	2	262
AN UNUSUAL PATELLA. By G. O. Tippett, F.R.C.S.	3	263
UNDIAGNOSED LESIONS OF BOTH TIBIÆ. By R. H. Metcalfe, M.D., M.Chir., F.R.C.S.	3	263
ROTATIONAL DISLOCATION OF ATLAS ON AXIS. By F. G. St. Clair Strange, F.R.C.S.	5	265
DISORDERS OF THE TEMPOROMANDIBULAR JOINT. By J. L. Harrington, L.R.C.P., M.R.C.S., L.D.S. ..	6	266
ARTHROGRYPOSIS MULTIPLEX CONGENITA. By R. H. Sewell, Ch.M.	7	267
? GIANT CELL TUMOUR OF NECK OF RADIUS. By R. H. V. Hafner, F.R.C.S.	8	268
RESULT OF REMOVAL OF RIGHT LUNATE BONE (SEMILUNAR) EIGHTEEN YEARS AGO. By W. E. Tucker, F.R.C.S.	8	268
List of other Cases shown	8	268
May No. Meeting Dec. 4, 1956		
INFANTILE CORTICAL HYPEROSTOSIS; A REVIEW OF THE CLINICAL AND RADIOGRAPHIC FEATURES. By John Caffey, M.D.	9	347
June No. Meeting Feb. 5, 1957		
THE PROBLEM OF THE TRANS-CERVICAL FRACTURE [*Abridged*]. By Denys Wainwright, F.R.C.S.Ed.	17	387
Film: CHEMOPALLIDECTOMY. By Dr. Irving S. Cooper (shown by Mr. R. C. F. Catterall)	18	388
THE RELIEF OF PAIN IN PAGET'S DISEASE (OSTEITIS DEFORMANS) [*Abridged*]. By Roy H. Maudsley, F.R.C.S.	18	388
HYDROCORTISONE IN TENNIS ELBOW—A CONTROLLED SERIES [*Abridged*]. By R. A. J. Baily, M.B., F.R.C.S., and B. H. Brock, M.B., F.R.C.S.. .	19	389
August No. Meeting March 23, 1957		
Meeting at King's College Hospital, London		
List of Cases, Demonstrations and Papers read	21	571
August No. Meeting April 2, 1957		
CHANGING PATTERNS IN SKELETAL AND ARTICULAR TUBERCULOSIS. President's Address by E. Stanley Evans, C.B.E., F.R.C.S.	21	571
August No. Meeting June 15, 1957		
Meeting at Lord Mayor Treloar Hospital, Alton		
List of Papers read	26	576
October No. Meeting May 7, 1957		
SYMPOSIUM: THE USE OF METAL IN BONE SURGERY	27	837
Mr. G. K. McKee	27	837
Mr. John Charnley	30	840
Mr. J. H. Hicks	32	842
Dr. J. M. Zarek	35	845
Section of Orthopædics with Section of Physical Medicine (*JOINT MEETING No.* 1)		
March No. Meeting Oct. 18, 1956		
DISCUSSION ON THE PRESENT POSITION OF MANIPULATIVE TREATMENT ..	—	137
Sir Reginald Watson-Jones ..	—	137
Dr. H. A. Burt	—	139
Dr. Guy Beauchamp	—	141
Dr. A. T. Richardson	—	142

Section of Otology

	PAGE Sect.	Vol.
April No. Meeting Nov. 2, 1956		
Presidential Address (*By Title*) ..	1	217
April No. Meeting Dec. 7, 1956		
DISCUSSION ON NOISE AND ITS EFFECTS	1	217
Dr. J. D. Hood	1	217
Professor W. Burns	6	222
Mr. D. E. Broadbent	9	225
April No. Meeting Feb. 1, 1957		
Discussion (*By Title*)	12	228
June No. Meeting March 1, 1957		
List of Papers read	—	414
September No. Meeting May 3, 1957		
THE PRINCIPLES AND PRACTICE OF BONE CONDUCTION AUDIOMETRY: A REVIEW OF THE PRESENT POSITION. By J. D. Hood	13	689
RECENT WORK ON THE BIOCHEMISTRY OF THE LABYRINTHINE FLUIDS. By L. Citron and D. Exley	21	697
Section of Otology with Section of Laryngology		
Joint Summer Meeting held at the University of Bristol OTOLOGICAL SESSION		
September No. Meeting June 27, 1957		
Discussion and Papers (*By Title*) ..	26	702

	PAGE Sect.	Vol.
LARYNGOLOGICAL SESSION		
September No. Meeting June 28, 1957		
Papers and Discussion (*By Title*) ..	26	702
September No. Meeting June 29, 1957		
Film (*By Title*)	26	702
Section of Otology with Section of General Practice		
(*JOINT MEETING No.* 2)		
June No. Meeting Feb. 1, 1957		
DISCUSSION ON RECURRENT OTITIS MEDIA IN CHILDREN	—	405
Mr. Lionel Taylor	—	405
Dr. I. Friedmann	—	406
Dr. G. F. Abercrombie	—	409
Dr. David Wheatley	—	410
Mr. S. R. Mawson, Mr. A. G. Tresidder, Dr. L. Roodyn ..	—	412
Mr. S. W. Allinson, Dr. G. O. Barber, The Chairman, Mr. F. C. W. Capps, Mr. G. H. Bateman, Mr. J. F. Lipscomb, Dr. R. Goulding	—	413
Dr. L. W. Batten, Mr. J. W. S. Lindahl, Mr. Lionel Taylor, Dr. D. Wheatley, The Chairman	—	414
Section of Pædiatrics		
May No. Meeting Nov. 23, 1956		
CONGENITAL AGRANULOCYTOSIS. By J. R. K. Henry, M.B., D.C.H. (for J. P. M. Tizard, M.R.C.P.) ..	1	329
OBSTRUCTIVE JAUNDICE AND SEPSIS FOLLOWING EXCHANGE TRANSFUSION FOR GROUP B INCOMPATIBILITY. By Leslie G. Andrews, M.B., D.C.H. (for J. P. M. Tizard, M.R.C.P.)	1	329
DIASTEMATOMYELIA. By J. P. M. Tizard, M.R.C.P.	2	330
BRACHIAL PLEXUS PALSY ASSOCIATED WITH SOFT TISSUE ATROPHY IN THE SCAPULAR REGION. By J. P. M. Tizard, M.R.C.P.	2	330
ACROGERIA. By David Morris, M.R.C.P.	2	330
PERIODIC NEUTROPENIA—A FAMILY STUDY. By T. J. Parkinson, M.R.C.P., and B. W. Meade, M.D. (for Mary J. Wilmers, M.D.) ..	3	331
LETTERER-SIWE DISEASE TREATED WITH PREDNISONE. By Eva A. Frommer, M.B., B.S., D.C.H. (for W. Mestitz, M.D.)	4	332
MULTIPLE CONGENITAL NERVE PALSIES. By Clive Upjohn, M.D. (for J. N. O'Reilly, D.M.)	5	333
PERIPHERAL DYSOSTOSIS. By S. D. V. Weller, M.D., M.R.C.P.	6	334
September No. Meeting Feb. 22, 1957		
Meeting at Queen Charlotte's Maternity Hospital, London		
DEMONSTRATIONS	7	705
CLINICAL DEMONSTRATION	7	705
I. Galactosæmia with Hyperbilirubinæmia Treated by Exchange Transfusion. By Dr. A. P. Norman	8	706
II. Galactosæmia. By Dr. A. White Franklin and Dr. Isobel Smith	8	706
III. Galactosæmia. By Dr. A. White Franklin	9	707
IV. Congenital Familial Spherocytosis with Neonatal Hyperbilirubinæmia Treated by Exchange Transfusion. By Dr. I. Smith and Dr. A. White Franklin	9	707
V. Congenital Extra-hepatic Biliary Obstruction, Bile Peritonitis, Choledochoduodenostomy. By Dr. A. White Franklin and Mr. R. S. Corbett	10	708
VI. Intra-hepatic Calcification, Staphylococcal Liver Abscess, following ? Occult Umbilical Sepsis. By Dr. A. White Franklin	11	709
The Place of the Pædiatrician in the Maternity Hospital. By Alfred White Franklin, M.B., F.R.C.P.	11	709
A Historical Note on Queen Charlotte's Maternity Hospital and Its Pædiatricians. By L. E. Turner, F.H.A.	13	711
Hæmolytic Disease of the Newborn: (1) Serology. By John Murray, M.D.	13	711
(2) Clinical Aspects of Exchange Transfusion. By A. P. Norman, M.D., F.R.C.P. ..	14	712
September No. Meeting March 22, 1957		
SEXUAL PRECOCITY, ADVANCED BONE AGE AND SKIN PIGMENTATION. ? McCUNE - BRUCH - ALBRIGHT SYNDROME. By Bruno Gans, M.D., M.R.C.P.	15	713
EOSINOPHILIC LEUKÆMIA IN EOSINOPHILIC FAMILY. ? LARVA MIGRANS SYNDROME. By A. A. Cunningham, M.D., M.R.C.P., and F. R. Ellis, M.D.	16	714

	PAGE Sect.	Vol.
DIVERTICULUM OF THE HEART. VENTRICULAR EXTENSION INTO THE ABDOMINAL WALL WITH LARGE VENTRAL HERNIA. By Patricia Woolf, M.B., B.Ch. (for R. H. Dobbs, M.D., F.R.C.P.)	19	717
HUNTINGTON'S CHOREA. By R. C. Roxburgh, M.D., M.R.C.P. (for C. T. Potter, M.D., F.R.C.P.) ..	19	717
NEONATAL ADDISON'S DISEASE. By G. R. Sparrow, M.B., B.S., D.C.H. (for J. Sakula, M.D., M.R.C.P., D.C.H.)	21	719
HEPATO-LENTICULAR DEGENERATION (WILSON'S DISEASE). By J. J. Kempton, M.B.E., M.D., M.R.C.P., D.C.H.	21	719
CUTIS LAXA. By M. E. Cashman, M.B., Ch.B., D.C.H. (for J. J. Kempton, M.D., M.R.C.P.) ..	21	719
October No. Meeting May 24, 1957		
DISCUSSION ON THE PROBLEMS OF SPINA BIFIDA CYSTICA	23	737
Dr. D. MacCarthy and Dr. Mary Lindsay	23	737
Mr. G. H. Macnab..	24	738
Mr. D. F. Ellison Nash	26	740
Dr. L. Guttmann [*Summary*] ..	28	742
Dr. K. M. Laurence, Mr. A. N. Guthkelch, Mr. G. H. Macnab	31	745
Dr. Hugh Jolly (*summing up*) ..	32	746
November No. Meeting April 26, 1957		
AN OUTBREAK OF INFANTILE GASTRO-ENTERITIS (*E. coli O.128*) IN A SMALL HOSPITAL MATERNITY UNIT. By R. M. Mayon-White, M.D., Ph.D., M.R.C.P., D.C.H.	33	927
NEONATAL ŒSTROGEN EXCRETION AND ITS RELATION TO POST-NATAL WEIGHT LOSS. By Bruno Gans, M.D., M.R.C.P., and J. C. Thompson, B.Sc., Ph.D.	35	929
December No. Meeting April 26, 1957, *contd.*		
THE CHANGING ÆTIOLOGY OF ERYTHEMA NODOSUM IN CHILDREN [*Summary*]. By John Lorber, B.A., M.D., M.R.C.P., and T. Colver, M.D.	37	1023
December No. Meeting June 15, 1957		
Meeting Held at the Children's Hospital, Birmingham		
List of Cases and Specimens shown ..	37	1023
CINE-ANGIOCARDIOGRAPHY IN ACYANOTIC HEART DISEASE OF INFANCY. By R. Astley, M.D., D.M.R. ..	38	1024
THE ASSOCIATION OF ACUTE APPENDICITIS WITH INFECTIVE DIARRHŒA. By K. B. Rogers, M.D.	39	1025
THE TREATMENT OF JUVENILE THYROTOXICOSIS WITH POTASSIUM PERCHLORATE. By Professor J. M. Smellie	40	1026
DUODENAL OBSTRUCTION IN THE NEW-BORN. By A. Gourevitch, F.R.C.S.	40	1026

Section of Pathology

	PAGE Sect.	Vol.
January No. Meeting Oct. 16, 1956		
INJURY AS AN ÆTIOLOGICAL FACTOR IN TUBERCULOSIS. President's Address by Professor John W. S. Blacklock, M.D.	1	61
March No. Meeting Nov. 20, 1956		
THE INCIDENCE OF PRIMARY HEPATIC CARCINOMA IN CIRRHOSIS. By R. G. F. Parker, M.D.	9	145
PSEUDOCHOLINESTERASE IN EARLY INFANCY. By H. Lehmann, M.D., Ph.D., F.R.I.C., Josephine Cook, M.B., B.S., D.C.H., and Elizabeth Ryan, B.Sc.	11	147
August No. Meeting March 19, 1957		
SOME OBSERVATIONS ON THE EFFECT OF FATS ON BLOOD CLOTTING. By J. D. Billimoria, Eunice Lockey and N. F. Maclagan	15	623
STAPHYLOCOCCAL ANTIBODY IN OSTEOMYELITIS AND SUPPURATIVE ARTHRITIS. By Charles H. Lack	17	625

Section of Pathology with Section of Physical Medicine

(*JOINT MEETING No.* 3)

July No. Meeting Feb. 19, 1957		
DISCUSSION ON RHEUMATOID DISEASE	—	461
Dr. W. S. Tegner	—	461
Dr. Bruce Cruickshank	—	462
Dr. A. T. Richardson	—	466
Dr. L. E. Glynn, Dr. E. J. Holborow and Mr. G. D. Johnson	—	469
Professor D. H. Collins	—	471
Dr. Brian Lacey, Dr. John H. Glyn, Dr. H. J. Gibson, Dr. D. A. Brewerton..	—	472

Section of Pathology with Section of Epidemiology and Preventive Medicine

(*JOINT MEETING No.* 5)

October No. Meeting Jan. 15, 1957		
DISCUSSION ON ADENOVIRUS INFECTIONS..	—	753
Dr. B. E. Andrews and Dr. J. C. McDonald	—	753

	PAGE Sect.	Vol.
Dr. H. G. Pereira and Barbara Kelly	—	755
Dr. R. G. Sommerville	—	757
Dr. P. K. Hopper, Dr. C. H. Smith, Mr. Barrie R. Jones	—	758
Major R. J. C. Hart	—	760

Section of Physical Medicine

February No. Meeting Oct. 10, 1956

JOINT CONTRACTURES IN CHILDREN. By Denis Browne, F.R.C.S.	1	69
JOINT CONTRACTURES. By Trevor H. Howell, F.R.C.P.Ed.	2	70

March No. Meeting Dec. 12, 1956

DISCUSSION ON REHABILITATION IN THE ROYAL AIR FORCE	7	129
Sir Reginald Watson-Jones, Dr. Basil Kiernander	7	129
Squadron Leader P. J. R. Nichols	9	131
Squadron Leader J. L. Milligan	11	133
Squadron Leader C. B. Wynn Parry	12	134

May No. Meeting Jan. 9, 1957

DISCUSSION ON GENERALIZED ACHES AND PAINS FROM METABOLIC BONE DISEASE	15	371
Dr. G. Alan Rose	15	371
Dr. F. H. Lumb	17	373
Professor C. E. Dent	21	377

August No. Meeting April 10, 1957

DISCUSSION ON REFERRED PAIN	25	581
Dr. G. Weddell	25	581
Dr. G. Gordon	30	586
Dr. R. M. Mason	32	588

October No. Meeting Nov. 14, 1956

DISCUSSION ON THE CLINICAL AND RADIOLOGICAL ASPECTS OF SACRO-ILIAC DISEASE	35	847
Dr. M. Thompson	35	847
Dr. D. R. L. Newton	38	850
Dr. Ronald G. Grainger	42	854

Section of Orthopædics with Section of Physical Medicine

(*JOINT MEETING No.* 1)

March No. Meeting Oct. 18, 1956

DISCUSSION ON THE PRESENT POSITION OF MANIPULATIVE TREATMENT	—	137
Sir Reginald Watson-Jones	—	137
Dr. H. A. Burt	—	139
Dr. Guy Beauchamp	—	141
Dr. A. T. Richardson	—	142

Section of Pathology with Section of Physical Medicine

(*JOINT MEETING No.* 3)

May No. Meeting Feb. 19, 1957

DISCUSSION ON RHEUMATOID DISEASE	—	146
Dr. W. S. Tegner	—	461
Dr. Bruce Cruickshank	—	462
Dr. A. T. Richardson	—	466
Dr. L. E. Glynn, Dr. E. J. Holborow and Mr. G. D. Johnson	—	469
Professor D. H. Collins	—	471
Dr. Brian Lacey, Dr. John H. Glyn, Dr. H. J. Gibson, Dr. D. A. Brewerton	—	472

Section of Proctology

April No. Meeting Jan. 9, 1957

CARCINOMA OF PELVIC COLON. SECONDARY DEPOSIT IN LEFT URETER SIMULATING A PRIMARY TUMOUR. LEFT HYDRONEPHROSIS. By H. R. Thompson, F.R.C.S.	1	269
"WEAVER'S BOTTOM" (ISCHIAL BURSITIS). By David Bailey, M.Chir., F.R.C.S. (for IAN TODD, M.S., F.R.C.S.)	2	270
INTUSSUSCEPTION OF APPENDIX SIMULATING A CARCINOMA OF THE CÆCUM. By Frank Forty, F.R.C.S.	3	271
STENOSED SEGMENT OF DESCENDING COLON ASSOCIATED WITH TRAUMA. By Rupert Corbett, M.Chir.	3	271
POTASSIUM-SECRETING TUMOUR OF THE COLON. By Cyril Cooling, F.R.C.S., and David Marrack, M.D.	4	272

June No. Meeting Feb. 13, 1957

DISCUSSION ON ARGENTAFFINOMA	7	443
Dr. P. S. Macfarlane	7	443
Mr. Adam N. Smith	9	445
Mr. I. S. R. Sinclair	11	447
Dr. E. Boyland and Dr. D. C. Williams	15	451
Professor D. F. Cappell	16	452

August No. Meeting March 12, 1957

HISTORY OF EXCISION OF THE RECTUM [*Abridged*]. By R. P. Warren, F.R.C.S.	17	599

[*May* 7, 1956]

SYMPOSIUM ON ANTI-TUMOUR AGENTS

First Session: Cytostatic Agents

Chairman—E. E. POCHIN, M.D., F.R.C.P.

Dr. Walter Davis (Chester Beatty Research Institute): *Chemical Structure and Biological Activity of the Cytostatic (Alkylating) Agents*

The chemotherapy of cancer presents the chemist with a different problem from that which faces those tackling the chemotherapy of the microbial diseases for we are all the time attempting to attack the tumour which is, more correctly, the effect rather than the cause of the pathological condition. Whereas the criterion of effectiveness of drugs being used against parasites or bacilli, for example, is simply their ability to kill or prevent reproduction of a foreign organism, the anti-tumour drug must be able to inhibit the growth and ultimately to destroy or disperse a tumour that in so many aspects of its behaviour and metabolism is scarcely distinguishable from the normal tissues from which it has sprung. This presents an immediate and practical problem of a test system capable of guiding the synthetic programme by giving indications of comparative effectiveness of each new drug that is made. Ideally what is wanted is some quantitative comparative test that can either compare equal activity at different dose levels or, alternatively, greater or less activity of similar doses of different drugs. In this present field we labour under the constant difficulty that test systems—and it is generally agreed that there is no test system better than experimental tumours for screening drugs of this type—are not very susceptible to providing graded quantitative results. For example, several compounds are now known which completely inhibit the Walker rat carcinoma, so that it is difficult to discriminate between them by their action on this tumour. On the other hand the Crocker sarcoma 180 is almost unaffected by a number of drugs which do appear to have some potential clinical application against Hodgkin's disease and chronic leukæmias. It is against this background that we shall attempt to discuss correlation of chemical structure with biological activity and therefore we shall sometimes be guilty of making what are more strictly subjective than statistical estimates of differing effectiveness of closely related compounds.

The measure of biological activity of these drugs is their power to inhibit the transplanted Walker rat carcinoma.

All the compounds that we are discussing here are chemically classed as alkylating agents but we should stipulate that they do not all produce the same biological effects and it is probable that even where the same type of effect is observed it would be unwise to assume that the same mechanism of action is involved. But the fact that these compounds are all capable of chemical reaction under physiological conditions does make it worth while recalling Ehrlich's classical theory of chemoreceptors that are blocked by reaction with drugs. A great deal of time has been devoted to *in vitro* studies of alkylation reactions between these drugs and functional groups that are present in living tissues and they are certainly capable in many cases of alkylating amino groups, carboxylic acid and phosphoric acid groups, for example, that occur abundantly in nucleoprotein. It is possible to build speculative theories that this type of chemical reaction is responsible for the observed biological effects, as for example the chromosomal aberrations, so frequently seen in tissue that has been treated with these drugs.

At any rate, this approach—the possibility of chemical reaction with naturally occurring functional groups—does provide the organic chemist with some rationale for investigating other types of reagents, capable of attaching themselves chemically under physiological conditions. Within any one series, the smaller structural changes that lead to a variation in biological activity can also provide a guide to the organic chemist for fruitful research. The type of alkylating agent that we shall be mainly discussing is the nitrogen mustards since we have devoted most time to their study. Early in the last war the studies of the possible effects of nitrogen mustard as a war gas (Fig. 1) led to the observation of its effect on the leucocytes which, in turn, led to its quite useful application in the treatment of Hodgkin's disease and the chronic leukæmias (Philips, 1950).

Because there were clinical difficulties associated with the use of HN2, a search was begun for a drug that was as effective against the lymphadenopathies but more moderate in its side reactions. This led to the development of the aryl as distinct from alkyl-halogenoalkyl-

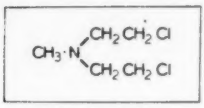

FIG. 1.—HN2.

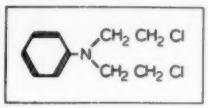

FIG. 2.

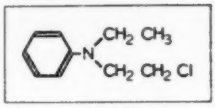

FIG. 3.

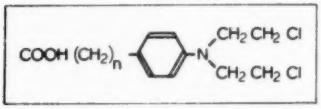

FIG. 4.—CB 1348 (n = 3).

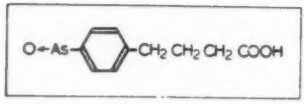

FIG. 5.

amines as potential anti-tumour drugs (Fig. 2) and this constitutes the first major structural change that resulted in a profound modification in the characteristics of the resulting drugs. Whereas the dichloroethylalkylamines were vesicant compounds that could only be administered by careful intravenous injection, the corresponding aryl compounds were mild enough for oral administration (Matthews, 1950). Chemically the distinction between these two series centres on the considerable difference in basicity of the parent amines and consequently difference in the reactivity of the chlorine atom. Throughout the nitrogen mustard group in both aryl and alkyl series, the most essential structural feature is undoubtedly the so-called bifunctionality. None of the many monochloroethylamines (Fig. 3) that have been tested have been found to have any activity whatsoever against experimental tumours. There has been much speculation on the significance of the need for the two chloroethyl arms to which the early theory of "cross-linking" made an important contribution (Goldacre *et al.*, 1949), but apart from asserting the need I do not intend to discuss its significance here.

Within the aryl-halogenoalkylamine series a very good correlation was soon established between chemical reactivity of the molecule and biological activity. For example, alteration in the *para*-substituents of the nitrogen mustard derived from aniline (Fig. 2) could be used either to increase or decrease the reactivity of the chloroethylamine group (Ross, 1949). Those substituent groups such as methyl, methoxy, or amino, which are electron-donating, increase the chemical reactivity—which can be conveniently determined by the hydrolysis rate of the compound—and produce active compounds. Electron-attracting substituents like chlorine, unionized carboxyl, phenyl or nitro reduce the hydrolysis rate to a very low order, and correspondingly, the compounds are inactive. Of course, these changes do more than merely affect the basicity of the nitrogen and hence the reactivity of the chlorine. The introduction of a basic amino group or a carboxylic (acidic) group into the molecule is bound to alter the conditions under which the drug might be adsorbed, whilst the latter group, in particular, profoundly alters the aqueous solubility of the drugs.

This introduces the conception that the part of the molecule other than the chloroethylamine group may be so chosen that whilst perhaps neither enhancing nor detracting from the fundamental activity of the drug it may greatly influence its arrival at its site of action. It was with this aim in view that the carboxyalkyl derivatives of the aniline mustard (Fig. 4) were synthesized, the introduction of the terminal carboxyl group having, as well as its acidic property, a solubilizing influence on the molecule. Within this series there appears to be an interesting variation amongst the five members of the series that have been made and tested. The first member derived from *p*-aminobenzoic acid, is of a low order of chemical reactivity, but still comes within the range that is associated with biological activity. The other members of the series (Fig. 4; n = 1–4) derived from *p*-aminophenylacetic acid (n = 1), propionic acid (n = 2), butyric acid (n = 3) and valeric acid (n = 4) all of which have a high and similar chemical reactivity, show a quite significant alternation in their level of biological activity. The most active member of the group is di-2-chloroethylaminophenylbutyric acid (n = 3) (now fairly well known as CB 1348) (Everett *et al.*, 1953). For two reasons it is tempting to ascribe this high level of activity to the specific structure of the molecule. Firstly in his study of trypanocidal drugs, Eagle found the most active one in a similar series of carboxyalkylphenyl arsenoxides (Fig. 5) was the butyric acid derivative, and secondly when we synthesized a comparable series of phenoxyalkyl compounds (Davis *et al.*, 1955) it was the phenoxypropionic acid derivative (Fig. 6) which is isoteric with CB 1348 which was the most active in a similarly alternating series. It may be no more than a particularly favourable surface activity which enables this particular drug to circulate and penetrate within an organism that endows it with its favourable therapeutic activity, for its chemical reactivity is no different from the other members of the series.

Another group of compounds in which variants of the carrying structure, which have little or no influence on the chemical reactivity of the chloroethylamine group, have been synthesized is the group related to naturally occurring substances. As examples of this type we have

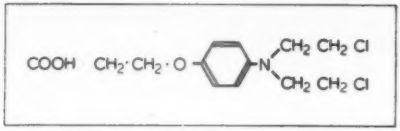

FIG. 6.

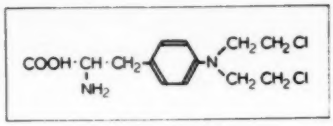

FIG. 7.—CB 3007.

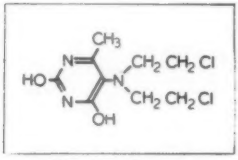

FIG. 8.—Dopan.

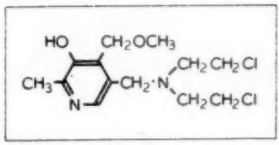

FIG. 9.

dichloroethylaminophenylalanine (Fig. 7) (Bergel and Stock, 1954; Larionov *et al.*, 1955) which is related to the naturally occurring amino acid phenylalanine. A pyrimidine type is exemplified by 2 : 6-dihydroxy-4-methyl-5-di-2′-chloroethylaminopyrimidine (Fig. 8)—known as Dopan (Larionov, 1956). A third example (Fig. 9) is a derivative of pyridoxine carrying a chloroethylamine group (Stock *et al.*, 1951). It is possible that the biological activity of these compounds which is of relatively high order, might be attributable to the incorporation of the whole molecule into a natural metabolic process in which, at first, only the carrying structure is involved and thus the chloroethylamino group is carried into a particularly susceptible part of the organism.

The search for a method by which compounds of this type might be endowed with some level of selectivity led into the interesting field of what we may call "latent activity" types. As we mentioned earlier it is possible to produce an aniline nitrogen mustard (Fig. 2) that is inactive, by introducing electron-attracting substituents, particularly in the *para* position. If such a group could be found which under *in vivo* conditions might be converted to either a neutral or electron-donating group, then it should be possible to synthesize a drug that would be inactive until such a chemical conversion had taken place within the organism. Just such a series are the nitrogen mustards derived from *p*-aminoazobenzene (Fig. 10A)

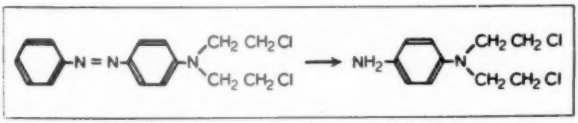

FIG. 10A.

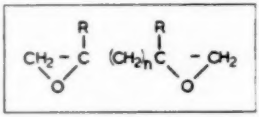

FIG. 10B.

FIG. 11.

(Ross and Warwick, 1956*a*). You will recall that the activity of Prontosil depends on the reduction of the azo group to give the sulphanilamide which is the active bactericide. Similarly the dichloroethylaminoazobenzene which has a hydrolysis rate so low as to ensure inactivity, would yield on the reductive fission of the azo group the highly reactive dichloroethyl derivative of phenylene diamine (Fig. 10B), which is biologically active. The development of this series by the introduction of substituent groups on the benzene rings particularly *ortho* to the azo linkage has produced a number of compounds in which enhanced activity is found in just those drugs where the substituent groupings will tend to assist the ease of fission of the azo linkage. In fact, comparison of the reduction rate of the azo linkage by the xanthine xanthine-oxidase system with biological activity in the series shows a very good correlation between high reduction rate and high biological activity (Ross and Warwick, 1955, 1956*b*).

I want to mention other alkylating agents that have been found to possess similar biological activity. The diepoxides (Fig. 11) are certainly alkylating compounds and capable of reacting with the same sort of active functional groups as the nitrogen mustards (Fraenkel-Conrat, 1944; Ross, 1953). The necessity for two epoxy groups within the molecule is an important link between the two series and gave strength to the early ideas of cross-linking mechanisms being an important part of their mode of action (Goldacre *et al.*, 1949). In this series the substituent groups on the α- and β-carbon atoms which reduce the reactivity of the epoxide ring also reduce biological activity. The most active compound in this series is the shortest molecule, the one derived from butadiene (Fig. 11; n=0). The extending of the inter-epoxy distance by a methylene chain produces compounds of diminishing activity as the methylene chain increases in length.

There is a similar chain-lengthening effect observed in the series of the dimethanesulphonyl esters (Fig. 12) of which Myleran is the best-known member. In this series, the most active compounds are those where the number of methylene units separating the two ester groups is four and five. Below four and above five activity rapidly falls away (Haddow and Timmis, 1953). The alkylating power of the dimethanesulphonyl esters can be altered by substituents on the end groups of the methylene chain, and such changes are accompanied by modification of the biological activity. Changing the methyl radical of the methanesulphonyl group for the *p*-toluyl radical has little effect on the rate of hydrolysis, but the resulting compound is biologically inactive. To refer back for a moment to the nitrogen mustard series, there was a group of compounds synthesized to test the importance of proximity of the two chloroethyl arms in the molecule by making chloroethyl diamines in which the two amino groups, each carrying one chloroethyl arm, could be separated by a

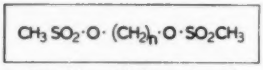

FIG. 12.—Myleran (n=4).

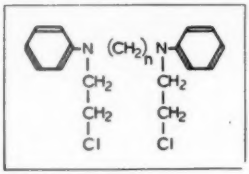

FIG. 13.

variable number of methylene groups (Fig. 13). All these compounds were chemically reactive but biological activity was lost when the methylene chain was increased beyond four units (Kon and Roberts, 1950).

That there should be three different types of alkylating compounds all requiring bifunctionality for anti-tumour activity and all exhibiting this additional structural requirement of an optimum distance between the functional group certainly arouses the sort of speculation that led Ehrlich to propound his theories of the interaction between drug and the organism being affected.

I have done no more than hint at the chemical theories that have been proposed to explain the observed biological activity of this type of compound. Perhaps the most attractive are those which depend on the drug penetrating the nucleus, reacting directly with nucleoprotein and so disturbing the subsequent behaviour of the chromosomes. On the other hand, it may be that alkylation of essential metabolic precursors causes the subsequent aberrations. If this were the case, we should be producing what could best be described as *in vivo* anti-metabolites.

Dr. A. L. Walpole (Imperial Chemicals (Pharmaceuticals) Ltd.) referred to work with which he had been associated upon the biological effects of a series of alkylating agents rather similar in properties to the nitrogen mustards. With these substances, of which triethylenemelamine (T.E.M.) was the best-known example, activity depended upon the presence in the molecule of one or more ethyleneimino groups. In this series, as with nitrogen mustards and epoxides, tumour-inhibitory activity was in general limited to polyfunctional compounds, i.e. compounds containing more than one reactive or "functional" group in the molecule—here more than one ethyleneimino group. On the other hand he had shown that carcinogenic activity was not so limited. With several monofunctional ethyleneimine derivatives, e.g. N-acetylethyleneimine, subcutaneous

sarcomata were readily induced in rats or mice, although the substances in question were not tumour-inhibitory. Monofunctional ethyleneimines were known, however, which, contrary to the general rule, inhibited the growth of experimental tumours, and exceptions of this kind merited perhaps more attention than they had received. In this connexion the tumour-inhibitory activity of ethyl methanesulphonate ($CH_3SO_2OC_2H_5$), reported by Professor A. Haddow, was of considerable interest.

Referring to the contrast between the dramatic effects of some anti-tumour agents upon experimental tumours and the severe limitations to their usefulness, particularly against solid tumours, in man, Dr. Walpole suggested that it was instructive to envisage three types of selective toxicity, directed respectively towards (*a*) all dividing cells, normal or neoplastic, within the body; (*b*) cells of or arising from one or other tissue; and (*c*) neoplastic cells as such. Available anti-tumour agents, of both the cytotoxic and anti-metabolite class, were possessed in large measure of a selective toxic action of the first type. By virtue of this they inhibited growth of the rapidly growing animal tumours commonly used for "screening" but not that of much slower growing solid neoplasms in man, at levels of dosage below those which produced fatal damage in the more actively proliferating normal tissues, e.g. bone-marrow and intestinal mucosa, of their respective hosts. This was not the whole story, as different agents had, in addition, selective effects of type (*b*). Thus Myleran, for example, was particularly damaging to cells of the myeloid series and particularly effective in myeloid leukæmia. There was, however, no clear evidence of any substance having a toxic action preferentially directed towards neoplastic cells as such.

Professor J. F. Danielli (Department of Zoology, King's College, London) said that it was probable that in very many cases there was no single outstanding chemical difference between malignant cells and other normal cells of the body. If no such single major difference existed, it was necessary to find a chemotherapeutic procedure which could be capable of exploiting small differences between normal and malignant cells. Theoretically this could be done usefully by making the action of a drug depend simultaneously upon several variables. For example, most of the anti-tumour agents which had been developed based on the nitrogen mustards had been thought to owe their effect to their relatively selective activity upon cells which were approaching division. Now if, in addition to dependence upon this difference between tumour and many normal cells, we made activity of the drug dependent also upon enzymic activation of the drug and upon its active transport into a cell, we could expect to obtain much higher selectivity than could possibly be obtained by using only the difference between dividing and non-dividing cells. Preliminary experiments had shown that this procedure could be used in practice (Danielli, 1954; Hebborn and Danielli, 1956).

Professor Haddow had suggested that the most rational approach to tumour therapy would be based upon exploitation of the fundamental differences between a tumour cell and a homologous normal cell. It seemed likely that in many cases this fundamental difference was not primarily biochemical in nature, and that such biochemical differences as existed in many cases were secondary consequences of a more fundamental disturbance. Some light upon what was likely to be involved had recently been obtained by the transplantation of cell nuclei from cell to cell by micromanipulation. These experiments had shown that, whereas a cell nucleus controlled the nature of the macromolecules available to the cell, in many instances the way in which these molecules were built into functional units was determined by the cytoplasm. The cytoplasmic determinants probably owed their specificity more to their organization than to the properties of their constituent macromolecules. In so far as the difference between normal and malignant cells was to be found in a difference between the cytoplasmic determinants, we should have to reach a much deeper understanding of the nature of these determinants before a fundamental therapy would be possible (Danielli *et al.*, 1955).

Dr. Edith Paterson (Christie Hospital and Holt Radium Institute, Manchester): The large number of closely related cytostatic compounds becoming available for clinical trial requires that the screening on human malignant disease should be as accurate as possible. For example, are there any real differences in effect, or special indications for triethylene melamine compound with triethylene phosphoramide or triethylene thiophosphoramide?

Since the use of ultimate survival times after chemotherapy of patients with malignant disease is not at present a realistic measure, I have used the length of remission after treatment by a given compound compared in the same patient with the remission obtained by one of the more established compounds, such as HN2 in Hodgkin's disease. In this way, the relative values of new compounds can be determined if care is taken that some patients are treated

by the new compound before, and some after, a trial of a more established compound. I use a method of obtaining a "clinical index" for the effects of a compound. This is based on an assessment of the change, beneficial or otherwise, in each presenting symptom at the time of treatment. I feel that this is more accurate and more specific in establishing the clinical effects and, therefore, the relative merits of a new compound, than is a clinical impression. Both methods of assessment should be in general agreement if the basis of the scoring system is sound.

Second Session: Anti-Metabolites

Chairman—Professor F. BERGEL, D. Phil.Nat., Ph.D., D.Sc., F.R.I.C.

Dr. George Bosworth Brown (Sloan-Kettering Institute for Cancer Research, New York): *Structure-Activity Relationships*

The evidence, which has been recently reviewed (Brown, 1954, 1956), that analogues of the larger molecules which can serve as polynucleotide precursors may have a chance of more selectively inhibiting specific tissues was discussed. Some of the biochemical pathways by which purines, nucleosides and nucleotides can be incorporated into the nucleic acids were outlined. The facts which indicate that certain unnatural analogues can be handled by the same enzymes which catalyze some of those reactions were summarized, as was that which suggests that certain anti-metabolites may be incorporated into polynucleotides *in lieu* of the normal components. Particular emphasis was placed upon evidence which suggests that certain inhibitory analogues (notably 2,6-diaminopurine and 9-β-*D*-ribofuranosyl purine) do not exert their anti-metabolite action by incorporation into polynucleotides, but that they may well do so through formation of analogues of ATP or of dinucleotide co-enzymes. Thus there are at least three "targets" for potential anti-metabolites of purine (or pyrimidine) derivatives: the functional, metabolically active, RNA; the DNA of the chromosomes; or those functional co-enzymes which are nucleotide in character.

Dr. Aaron Bendich (Sloan-Kettering Institute for Cancer Research, New York): *Structure-Activity Relationships*

More than 16,000 compounds and extracts of natural materials which comprise almost the entire gamut of organic chemical types, have to date been tested in the Division of Experimental Chemotherapy of the Sloan-Kettering Institute for possible anti-tumour or anti-leukæmic activity. Percentage-wise, there were more examples of active substances found among derivatives of the nucleic acids than in any other class of substances. Those active purine and pyrimidine derivatives which have been revealed in this way are, unfortunately, few in number. Other anti-tumour agents such as the anti-folics or azaserine, &c., have been found to interfere with the biogenesis of purines either for nucleic acid or for purine co-enzyme biosynthesis. These various compounds therefore appear to have nucleic acids or the purine-containing co-enzymes or ATP as their target and our programme of synthesis of anti-tumour agents has been designed with these factors in mind.

There are certain principles which, at least in part, have guided us in our synthetic efforts. These have been based on the few purine and pyrimidine derivatives which have proved to possess either an anti-tumour activity or were found to behave as anti-metabolites. Adenine (6-aminopurine) and guanine (2-amino-6-hydroxypurine) occur in all nucleic acids which have been examined and these are also components of various co-enzymes and of ATP. Very recently another purine has been isolated from deoxyribonucleic acids (DNA). This derivative of adenine is 6-methylaminopurine. Another compound of importance is hypoxanthine (6-hydroxypurine) and this, in the form of its 9-β-*D*-ribofuranosyl-5′-phosphate, occupies a central position in the biosynthesis of the naturally occurring purines. Among the purine derivatives which have shown an anti-tumour activity are 6-mercapto, 6-chloro, 2,6-diaminopurine, the parent, purine, itself and 8-azaguanine. In each of these cases, there is a single structural alteration when their structures are compared with the purines adenine, guanine or hypoxanthine. Thus, for example, 6-mercaptopurine may be considered as a simple derivative of either adenine or hypoxanthine involving just a single change in structure at position 6 of the purine nucleus. The same can be said for 2,6-diaminopurine. The latter compound can be considered to be an analogue of adenine in which the hydrogen at position 2 has been replaced by an amino group or, alternatively, as an analogue of guanine in which the 6-hydroxyl of guanine has been replaced by an amino group. Similarly, 6-chloropurine or purine itself may be visualized as a structural analogue of adenine involving a single structural alteration. Replacement of carbon No. 8 of guanine by nitrogen affords the compound 8-azaguanine. Whereas these analogues show an activity

against one or another rat or mouse tumour, only 6-mercapto- and 6-chloropurine have shown a clinical interest.

However, a second structural change in the active purine derivatives yields compounds which are inactive as anti-tumour agents. For example, 8-azapurine or 8-aza-6-mercaptopurine are quite inactive in this regard. These structural relationships constitute the basis of some of the principles which have guided us in our synthetic experiments in the purine and pyrimidine series and in the nucleoside derivatives as well.

It would probably be a serious error if we were very rigid in our ideas in this field. These active compounds, although very encouraging, are very few in number, and may be too few from which to draw hard and fast rules. Furthermore, we know very little as to the actual mechanism of their action. Hence, we should not rule out other possibilities even though they may violate our tentative guiding principles. One example of this is the compound 6-methylpurine which is one of the most toxic agents which has been studied in the Chemotherapy Division. It was thought that the 6-trifluoromethyl analogue (that is, the compound in which fluorine atoms have replaced all three hydrogen atoms of the methyl group in the 6-methylpurine) might be of interest. Although this new compound has turned out to be quite interesting from the pure chemical and physico-chemical standpoint, it was found to be non-toxic to animals at dose levels several hundred times larger than those of 6-methylpurine.

We must also not lose sight of the fact that a number of anti-tumour agents have resulted from a purely empirical testing approach. As we study the meagre fruits of the empirical testing programme, certain guiding principles emerge, one of which I have just mentioned. We should like to think that an exploitation of these principles might be characterized as an enlightened empiricism but it is quite clear that new principles have yet to be discovered. Although the nucleic acids and the purine co-enzymes still appear to be a very fruitful target for the chemotherapist, he should not shut his eyes to other possibilities because of preconceived notions.

Dr. Gertrude B. Elion (Wellcome Research Laboratories, Tuckahoe, New York): *Structure-Activity Relationships*

The optimal differential toxicity (therapeutic index) in a series of biologically active materials often depends on details of fine chemical structure in a manner which is revealed only by the preparation and testing of a series of related substances. Among substances which have anti-tumour activity the overall differential effect is often small and the chemical-biological patterns which emerge from such studies are often rudimentary as a result. On the whole such investigations tend to reveal chemical variations which result in inactivity rather than to suggest a series of chemical alterations in an active molecule which may lead to progressive improvements in therapeutic index. Nevertheless, the biochemist is an optimist and is never truly satisfied until he has explored a hundred or more variations for himself. I shall not discuss all of these variations but only indicate what effect some of the alterations in chemical structure have had on the activity of 6-mercaptopurine against sarcoma 180.

We are indebted for the tumour data to Drs. C. C. Stock and D. A. Clarke of the Chemotherapy Division of the Sloan-Kettering Institute. In Tables I and II the doses given are, in general, the maximum tolerated doses of the compounds.

Alkylation of any of the purine ring nitrogens led to a diminution or abolition of the anti-tumour effect of 6-mercaptopurine (Table I). Only the 1-methyl derivative retained any activity and this was of a borderline variety. In all cases, toxicity was decreased.

Introduction of other groups, e.g. SH, OH, CH_3, at positions 2 or 8 of the purine ring led, in general, to a reduction in toxicity and a loss of biological activity. This was not the case, however, for the 2-amino derivative. Thioguanine is about ten times as active as 6-mercaptopurine on sarcoma 180 as well as against adenocarcinoma 755 in our laboratory. However, this compound is also ten times as toxic for most experimental animals. In clinical trials thioguanine is only a little more active than 6-mercaptopurine and several times as difficult to make. An attempt to improve the chemotherapeutic index of thioguanine by substitutions of the amino hydrogens by alkyl or aryl groups led only to diminished activity (e.g. 2-CH_3NH), or to inactivity.

Substitution on the sulphur has produced, on the whole, less toxic compounds and some of these have retained considerable activity, particularly the methylmercapto and benzylmercapto compounds. A number of benzylmercaptopurines with various substituents in the benzene nucleus have been less active. The 6-methylmercaptopurine is now undergoing clinical trial.

An exploration of substituents other than sulphur on the 6-position (Table II) has thus far proved somewhat disappointing. The 6-methyl compound is very toxic but appears to have very little effect on the tumour size. Both the 6-bromo and 6-methylamino compounds show borderline activity. In this connexion it should be mentioned that 6-chloropurine has

been reported to be active on sarcoma 180 at doses of 500 mg./kg. Although the 6-CN and 6-COOH purines are inactive, compounds derived from these are being prepared and tested.

The relationship between structure and activity is actually more complicated than these results would indicate. The data presented have been for tumour inhibition in the usual eight-day period. However, tumour regression rate may be far more important. Tests for this type of activity have now been carried out and with one or two compounds the results are particularly striking. Thus purine-6-thioglucoside produces scarcely any inhibition of tumour growth in eight days at a dosage schedule which causes almost 100% regressions on longer holding. This compound is now entering clinical trial and it remains to be seen whether this type of effect on animal tumours has any relationship to clinical effectiveness.

Mr. G. M. Timmis (Chester Beatty Research Institute): *New Anti-folic Acids and Anti-purines*

Although the treatment of malignant disease with drugs having anti-folic acid activity has not been discussed here, these drugs are valuable in the treatment of acute leukæmia and have also produced some improvement in cases of breast cancer (Colsky, 1954) and in rhabdomyosarcomas (Colsky, 1954; Farber, 1954). That the drug action against leukæmia is at least closely related to an anti-metabolite effect, is indicated by the prevention of the normal effect of Methotrexate on a mouse leukæmia, by the administration of folic acid (Burchenal *et al.*, 1949). I would therefore like to mention very briefly the results of a recent investigation into anti-folic drugs (Felton and Timmis, 1955; Timmis *et al.*, 1957) wherein we have abandoned the sort of close structural analogy which relates, e.g., Methotrexate to folic acid, in favour of simpler structures (I and II, Fig. 1). The effect of compounds of these series on *Str. fæcalis* has been examined by Dr. H. O. J. Collier and Miss P. Huskinson and fairly marked anti-folic acid activity has been found in some cases; e.g. I, X=Y=NH_2, Z=4′-chloro- and II, X=Y=NH_2, Z=4′-chloro-, both give inhibition coefficients of about 90; still higher activities appear, when the benzene ring is replaced by naphthalene. Both X and Y must usually represent NH_2 groups before high activity is attained.

One reason for trying structure I was a degree of spatial resemblance to the simple pteridine structure (the ring-system of folic acid). Substances of structure II were initially made and tested because the facile *in vitro* oxidation of type I to type II indicated the possibility of a similar transformation *in vivo*. Although several anti-folics of high potency have been found amongst substances of type II the available evidence argues against the activity of type I being dependent upon an initial conversion of I to II (Fig. 1).

Some new types of purine analogues with anti-purine activity (described at the Ciba Symposium on the Chemistry and Biology of Purines, May 8–10, 1956) may also be mentioned.

Purine itself and certain simple derivatives such as 6-methyl- and 6-chloropurine are anti-purines (anti-adenine or anti-guanine) but exhibit, both clinically and in experimental animals, toxic side-effects. Furthermore, Dr. George B. Brown has shown that the attachment of a ribose moiety to purine or 6-methylpurine considerably enhances the toxicity. Since it has been established that the ribose moiety is attached to a precursor of purine in the biosynthesis of nucleic acid and remains attached throughout the nucleotide and nucleoside stages, a sugar residue had appeared to be a suitable residue to attach to a simple purine analogue. The possibility, however, of toxicity being thereby enhanced led us to

Dr. D. A. G. Galton (Chester Beatty Research Institute): *Clinical and Biological Aspects*

I propose briefly to consider, first, the relation between animal and human malignant disease in their response to therapeutic trials; second, the similarities and differences between cytostatic drugs and anti-metabolites from the clinical viewpoint; lastly I shall sketch in outline the therapeutic use of the main groups of anti-metabolites, especially in acute leukæmia.

A disturbing feature in the work of testing compounds for anti-tumour activity is that so many compounds are effective in laboratory animals but are without effect in a majority of human neoplasms. Dr. Walpole has discussed this matter and I endorse his views. The range of sensitivity in human malignant disease is narrow. With rare exceptions carcinomas are resistant to chemotherapy, as are malignant tumours arising in bone, connective tissue and the central nervous system. The only conditions that respond with any regularity to chemotherapy are the malignant lymphomas and leukæmias, and, less commonly, the even rarer neuroblastomas and rhabdomyosarcomas. The sensitive conditions differ in two respects from the resistant neoplasms. First, they are often generalized diseases involving comparatively large masses of abnormal tissue in relation to total body-weight: secondly the abnormal tissue often contains a high proportion of rapidly dividing cells. As a result of either or both of these circumstances the total nutritional requirements and metabolic turnover of these growths is substantial in proportion to the metabolic activities of the whole body. In contrast, carcinomas, although we usually think of them as rapidly growing, often grow surprisingly slowly, contain a very small proportion of actively dividing cells, and weigh very little in relation to total body-weight. Much of the metabolic activity of human carcinomas is concerned not only with increasing the bulk of the tumour but in efforts at differentiation which involve attempts at synthesizing substances like mucin or keratin. Now the common laboratory tumours of small animals, usually mice and rats, are frequently as large as or larger than the animals themselves. They are mostly undifferentiated growths containing a high proportion of rapidly dividing cells, and their growth rate is rapid compared with that of the host. A greater proportion of a given dose of the compound on trial is therefore likely to find its way to these animal tumours than in most human carcinomas where the amount likely to reach the growth must be infinitesimal. In the case of cytostatic drugs whose distribution throughout the body appears to be entirely random, the tumour is as likely as any other tissue to receive its share, but in the case of an anti-metabolite it will receive proportionately less than the rest of the body unless the tumour is very large or unless the metabolic process in question is so much more rapid in the tumour that the substance is selectively taken up by it, as the thyroid takes up iodine.

The poor vascularity of human carcinomas was often quoted as a major obstacle by those who saw no future in tumour chemotherapy. Tumours were known to be often largely necrotic and it was thought that no drug would ever reach the viable portions. In fact, carcinomas always receive enough blood to enable them to survive and to metastasize even though the survival of any particular mass is precarious. It is now an everyday occurrence to see widespread and bulky metastases from mammary carcinomas undergoing rapid regression during treatment with sex hormones. It is therefore likely that if the right compound were available it would reach the most remote growths following systemic administration. The possibility of obtaining selective uptake will depend on finding a difference between tumour behaviour and that of the rest of the body. No qualitative peculiarities of malignant growth have been demonstrated so quantitative differences will have to be exploited. It is in this respect that the study of antimetabolites would appear to offer better prospects than that of cytostatic agents.

Three groups of anti-metabolites have been tried clinically: they are antagonists of folic acid, of purines, and of amino acids. All are ineffective in the treatment of carcinomas but have been of some value in neuroblastomas, rhabdomyosarcomas and occasionally in reticulosarcomas. They are chiefly of value in the treatment of acute leukæmia for which they have now become the standard form of therapy.

In comparing anti-metabolites as a class with cytostatic drugs we find little overlap in their clinical activity. Some cytostatic drugs have limited efficacy in generalized mammary, ovarian and testicular carcinomas and their range of usefulness in lymphomas is greater than is the case with anti-metabolites. If we consider the leukæmias alone the two groups are again distinct. Thus, cytostatic agents are of little value in acute leukæmias but are really useful in the treatment of chronic leukæmias. Folic acid antagonists are useless in chronic leukæmias but induce remissions in about two-thirds of the cases of acute leukæmia in children; anti-purines are effective in acute leukæmia at all ages and have been used successfully in chronic myeloid but not in chronic lymphatic leukæmia. In acute leukæmia the folic acid antagonists act rapidly, the anti-purines more slowly. With both groups of drugs the bone-marrow must be rendered aplastic before regeneration of normal elements begins. Remission is often in progress two weeks after starting therapy with folic acid antagonists but may be delayed for eight to ten weeks when anti-purines are used.

Cytostatic drugs and anti-metabolites share the serious disadvantages that their beneficial effects always prove to be temporary in every condition in which they are used. In acute leukæmia especially, patients in remission often appear to be healthy in all respects, yet relapse is inevitable. Subsequent remissions may sometimes be obtained by repeating treatment but drug-resistance eventually blocks further therapeutic attempts. There is no cross-resistance between the major groups of chemotherapeutic agents which may therefore be employed successively but a patient who has become resistant to a particular drug will not usually respond to another member of the same group. In acute leukæmia folic acid antagonists, anti-purines, and corticotrophin or steroid hormones may all help to control the disease. In practice it is very difficult to know what to do once remission has been induced by a particular drug. The alternatives are to stop treatment and wait for relapse, and to give maintenance doses in the hope of averting relapse. A third possibility is to combine two drugs acting in different ways, a method which on theoretical grounds might be expected to delay the development of resistance, provided the patient is sensitive to both drugs (Boyland, 1956). Burchenal (1956) has treated a number of children with continuous administration for many months of full doses of 6-mercaptopurine simultaneously with small doses of azaserine. Remissions were maintained for rather longer than is usual when 6-mercaptopurine is used alone.

With new drugs of all kinds toxicity is often a major problem and cannot be predicted from the results in other species. The earlier cytostatic drugs submitted for clinical trial were often so toxic that the more pessimistic of us wondered whether the separation of therapeutic and toxic effects would ever be accomplished. The newer compounds including Myleran, thio-TEPA, CB 1348 and Colcemid are less difficult to handle. Most anti-metabolites have so far proved to be highly toxic but their effects, unlike those of cytostatic drugs, can sometimes be reversed by giving the specific metabolite against which they are acting.

Anti-metabolites, like many cytostatic drugs, frequently affect the gastro-intestinal tract, and some members of all groups induce nausea, vomiting, abdominal cramps and diarrhœa. But there are remarkable differences between individual compounds in each group. Amethopterin, the most useful member of the 4-amino-substituted folic acid antagonists in the treatment of acute leukæmia in children, causes bone-marrow depression, megaloblastosis, ulceration of buccal mucosa, gums, tongue, and later, diarrhœa. These effects can be reversed by citrovorum factor. An analogue of the anti-malarial Daraprim 2,4, diamino, 3-4,dichlorophenyl, 6-methylpyrimidine (Hitchings *et al.*, 1952) is also a folic acid antagonist which has been tried by Dr. Burchenal's group at Memorial Centre with some success in acute leukæmia. But it is very toxic, and like amethopterin causes bone-marrow depression with megaloblastic change, and diarrhœa. Buccal ulceration comes on much later than with amethopterin and nearly half the patients develop generalized skin rashes. In spite of these differences the toxic effects are also reversible by citrovorum factor (Murphy *et al.*, 1954).

The anti-purines show similar diversity in incidence of therapeutic efficacy and of toxic effects, and the relation between the two is just as difficult to explain. 6-mercaptopurine is the most useful drug clinically in acute leukæmia because it is practically non-toxic in therapeutically effective doses. Most other anti-purines are toxic in therapeutic doses. *Purine* itself (Philips *et al.*, 1954) is interesting because it is the only member of the group that damages lymphoid tissue. But clinically it causes VIII nerve deafness, generalized bullous erythema and loss of hair (Burchenal, 1956). *Puromycin amino-nucleoside*, a substance of antibiotic origin, has anti-purine activity but is not useful clinically because it damages the renal tubules with resulting gross albuminuria (Burchenal, 1956). It is clear that in calling these substances anti-purines we are selecting only one of several biological activities, and we may wonder whether it is the anti-purine activity that is responsible for the anti-leukæmic effects. Earlier, I noted the discrepancies between human and animal tumours in their response to chemotherapy. Human and animal leukæmias are also very different. Azaserine (Bartz *et al.*, 1954) for example, though very active against animal leukæmias proved disappointing when tried clinically (Ellison *et al.*, 1954). Even the

relative toxicities of compounds show surprising species differences. Thioguanine (Elion *et al.*, 1952) is twenty times as toxic as 6-mercaptopurine in dogs but the effective dose in humans is about the same for both drugs.

Both of the amino acid antagonists that have been tried clinically are very toxic. Ethionine, an analogue of methionine caused toxic psychosis and damage to liver, skin and gastro-intestinal tract (White and Shimkin, 1954). Selenium cystine (Weisberger and Suhrland, 1956), possibly acting as a cystine antagonist, caused severe nausea and vomiting, epilation, and separation of the nails from their beds. Selenium cystine is of particular interest because it is taken up more readily by leukæmic than by normal granulocytes (Weisberger *et al.*, 1956). Because of its toxicity it will probably be of little value in the treatment of leukæmia but this type of selective action may well prove to be the essential basis of the future therapeutic application of anti-metabolites.

Dr. F. G. J. Hayhoe (Department of Medicine, University of Cambridge): I fear that those of us who are working in this field, particularly in the chemical and experimental side, may be inclined to over-optimism, and I am not sure that some of the large-scale operations are not open to criticism. Dr. Bendich has told us, for example, that over 16,000 compounds have been obtained by synthesis or other means and investigated to determine their possible activity as purine anti-metabolites in the unit with which he is associated. This is an impressive number of compounds and speaks very highly for the imagination and technical ingenuity of the organic chemists, but it seems the reverse of complimentary to the medical and biological direction which should be guiding the search, since from these 16,000 compounds only one purine antagonist, 6-mercaptopurine, has proved sufficiently valuable to find a place in clinical practice. It is true that a number of other substances do manifest some anti-tumour activity and a few have found a place in clinical experimental trials, but the overall increase in our therapeutic armamentarium derived from this enormous programme of anti-purine synthesis has been very small indeed. Speaking from the point of view of a clinician I should not wish to appear ungrateful for even one active compound, and perhaps 6-mercaptopurine may be regarded as justifying a very great deal of time and energy in synthetic research, but the criticism is difficult to avoid that a very blunderbuss method of obtaining compounds of clinical value is being pursued. Perhaps the extensive researches which are being currently carried out on the intricacies of normal and neoplastic cell nucleoproteins may provide a more satisfactory lead in this matter.

A point of some clinical importance to which Dr. Galton has already referred, and which may one day be provided with a biochemical explanation, is the difference in reaction to certain anti-metabolites, in particular the folic acid antagonists, shown by children as contrasted with adults. Possibly more concentration on clinical and biological phenomena of this kind might have something to contribute to the study of cell sensitivity and resistance to anti-metabolites.

Dr. R. L. Worrall: It is not correct to state that there is no qualitative difference between cancer tissue and normal tissue. The report of a polarographic study by Carruthers and Suntzeff states that the fat of epidermal cancer tissue of mice is qualitatively different from the fat of normal mouse epidermis. Jean Verne reported autoxidation of liver fat in tumour-bearing rats, and the decrease of marrow fat in myeloid leukæmia may be due to this abnormal oxidative process. It is possible, moreover, that leukæmic cells assimilate autoxidizing marrow fat. It is commonly supposed that marrow fat decreases in myeloid leukæmia through normal processes of fat mobilization, but this is a pure assumption, not always recognized as such.

[*November* 2, 1956]

The Anæsthetist's Role in Undergraduate Training [*Abridged*]

PRESIDENT'S ADDRESS

By KATHARINE G. LLOYD-WILLIAMS, C.B.E., M.D., F.F.A.R.C.S.

IT is sometimes said that anæsthetics should be a post-graduate subject, some anæsthetists holding the view that it is waste of time for the students and bad for the patients to encourage undergraduates to give anæsthetics at all. This is an extreme view and one with which I heartily disagree, but there is a good deal of variation in the extent of undergraduate teaching in the different schools.

It is not difficult to get enthusiasm from students for such a specialty as anæsthesia. The administration of anæsthetics is essentially practical and almost every student likes to feel he is actually doing something. If he can be given the feeling that he is responsible for the patient, this again enhances his pleasure. Some thirty years of teaching anæsthetics has shown me that one can only expect to drive into the average student a few fundamental facts. Those who wish to reform medical education—and they are many—constantly say that all the students should be taught are the basic principles. This is unfortunately more easily said than done. It is only when one looks back over years of training and practice that one begins to be selective enough to see what *are* the basic principles. The first practical fact I think a student should learn is that from the moment he begins an anæsthetic, he is absolutely responsible for that patient until he regains control of his own airway and is breathing normally. In no other specialty to quite the same extent does a doctor hold the life of the patient in his hands. This cannot be reiterated too often. Though the anæsthetist does, in fact, depute his responsibilities to the sister or nurse in charge who is going to watch the patient recover in bed, he has no right to do so—and certainly would be very foolish to do so—*unless* he is satisfied that he is handing over his patient to a responsible deputy, that the patient is breathing normally, preferably with an airway, that he is a good colour, and has a satisfactory pulse and blood pressure. If the hospital or nursing home is a new one to him he should satisfy himself before he leaves the building that the patient is being satisfactorily watched and cared for. That this is not always done is manifest from reports of unfortunate accidents which appear from time to time in the Press.

The sense of responsibility can be impressed on the student by making him turn on the gas and oxygen machine himself, checking all cylinders, the bottles and their contents. In spite of the convenience of piped oxygen and nitrous oxide to operating theatres, I am very much averse to this system in theatres where undergraduates are being taught. To my mind it is totally wrong to encourage them to think that the responsibility for gases lies in the hands of porters or theatre orderlies outside the theatre. With the introduction of standard colours for cylinders, and non-interchangeable couplings for N_2O and O_2, risk of administering wrong gases is greatly reduced. The same applies to the checking of ampoules. One cannot impress it often enough on the administrator that what he draws up, mixes and injects is entirely his responsibility and that he cannot lay the blame for wrong injections on the sister, nurses or anyone else in the theatre. The standardization of colours for the cylinders, the non-interchangeable coupling, the new methods of marking ampoules to obviate mistakes, all help to make for safety for the patient but *nothing* takes the place of checking the cylinders and checking the ampoules.

Nothing makes me more angry than seeing a student take up a syringe of some fluid, possibly mixed by the resident, and prepare to give it to the patient. When you ask him what he is giving he has not an idea. I should like to emphasize the

importance of teaching students some simple method of local anæsthesia, ensuring that they know the strength of the drugs they wish to use and also the maximum therapeutic dose. Junior house-officers have in some hospitals refused to give anæsthetics because they are too frightened to do so. This is surely a condemnation of our teaching schools. I take the view that a qualified practitioner should be capable of administering some simple form of anæsthetic, both local and general, just as he is expected to remove a toe-nail, open an abscess, do a lumbar puncture or any other simple operative procedure. We cannot after all have specialists performing all the minor operations. But if we expect them to do these things, we must give them a basic training in really simple methods.

My own practice, horrifying as it may appear to some, is to teach undergraduates in the minor operation theatre to anæsthetize the patients with ethyl chloride and ether on a mask to the first plane of the third stage in the anæsthetic room, then to continue with gas and oxygen and ether from a standard machine in the operating theatre. The patients who are reasonably healthy and are not being treated as in-patients are given atropine pre-operatively and walk into the anæsthetic room. They are kept post-operatively in an out-patient ward for a few hours before going home. These out-patient sessions provide one of the best methods for teaching the undergraduate simple methods for the kind of small operation for which in the ordinary way a skilled anæsthetist is not called. As I grow older I find my teaching reduced to a few simple aphorisms, such as, "Keep the patient breathing, and keep the patient pink." Ether has sometimes been called a foolproof anæsthetic. If you give too much ether the patient stops breathing; fortunately with the heart and circulation still in a reasonable state. If you let a patient get blue you can let him die from anoxia at any stage whether under light or deep anæsthesia. The patient gets blue most commonly from obstruction of the airway. It should be reasonably easy to keep a clear airway but all teachers will know how students can hold a patient in such a way and with such good intentions that they successfully prevent the patient from taking a breath at all. Maintaining a clear airway is therefore one of the basic things that can most easily be taught in these sessions.

How to deal with the vomiting patient is also a salutary if disagreeable exercise. When the student has been helped with a case or two, it is possible to let him start on his own and only help him out of his difficulties when they arise. We must all have been shaken by the reports published this year of the number of patients who die as the result of inhaling vomit. I suggest very seriously that some of these patients might have been saved, not by the use of suckers, bronchoscopes or any elaborate procedure at all but by the simple knowledge of how to deal with a patient who is vomiting, by tilting him into the safest position, on his side and maintaining an airway. Here again ether, as a means of anæsthesia by the inexperienced administrator has great advantages over more elegant methods, in that fortunately the patient usually vomits at a stage at which he can still protect himself. His pharyngeal reflexes are still present and all that is needed is to put him into a position head downwards and preferably on his side, possibly with a pillow under his shoulders so that he is not likely to inhale vomit but will cough it up. The same position should be adopted when the patient is removed from the operating table to the trolley after minor operations. In the bad old days every nurse learnt how to deal in a simple way with a vomiting patient. To-day when on the whole patients seldom vomit after modern anæsthetics this complication, when it occurs, is often very badly dealt with.

My third aphorism is: "If a patient will retain an airway under ether anæsthesia he must have lost his pharyngeal reflexes and is therefore in the third stage, i.e. surgical anæsthesia."

If one can get a student to learn these three facts it will give him some confidence when called upon to give a simple anæsthetic i.e. (1) Keep the patient breathing. (2) Keep him pink. (3) If he will retain an airway he must be at any rate in the first plane of the third stage of anæsthesia.

I doubt if you can teach him much more in the undergraduate stage, but he has at least some basis to build on. The use of the gas and oxygen machine in the minor operating theatre is again good practice, though if the administrator is inexperienced it is infinitely safer to use ether on a mask than run any risks of giving an inadequate supply of oxygen to a patient.

Dental anæsthetics.—It is still very common practice for dental surgeons to ask the local general practitioner to give dental gases especially to their own patients. I have recently been sent the results of a questionnaire sent out by the British Medical Students' Association enquiring about the amount of instruction which undergraduates get in giving dental anæsthetics. There are many dentists who are certainly better able to give anæsthetics than the doctor and they sometimes complain that they have to start by teaching their medical colleagues.

This is not surprising when it is realized that some undergraduate schools give no instruction at all in this very important branch of anæsthetics. The possibilities of mishaps occurring in the dental chair are manifold, and every doctor should be aware of them and be given some basic training.

Intravenous injections.—Whether students should be encouraged to give intravenous anæsthetics is perhaps a moot point, but it cannot be denied that the anæsthetist is the best person to teach him to put a needle into a vein. Undergraduates are usually taught by the registrar or house-officer how to take blood for pathological tests during their introductory posts. The patient can be spared much if the anæsthetic staff will spend time on teaching undergraduates how to put a needle into a vein without causing misery to the patient. Which vein to use has been a matter of some controversy. There are some disadvantages in selecting the veins at the elbow. As Professor E. A. Pask has pointed out, there is the risk of damage to the median nerve (or even injection into the ulnar artery) and the veins of the back of the hand have been suggested as the best site. These are not always easy veins for the student to get into because they are more mobile and perivenous injections occur perhaps more frequently but fortunately more obviously. The veins in the ante-cubital fossa are usually better supported by the surrounding tissues and are more easily entered by the inexperienced. The use of veins on the ulnar side of the ante-cubital fossa for injection should never, however tempting, be taught to undergraduates. With the use of an eccentric nozzle on the syringe and the syringe resting on the arm, and with a definite routine for injection, the procedure can be acquired fairly quickly. There is a lot to be said for using the bevel of the needle facing downwards when teaching students (Fig. 1). If after entering the vein they let the needle

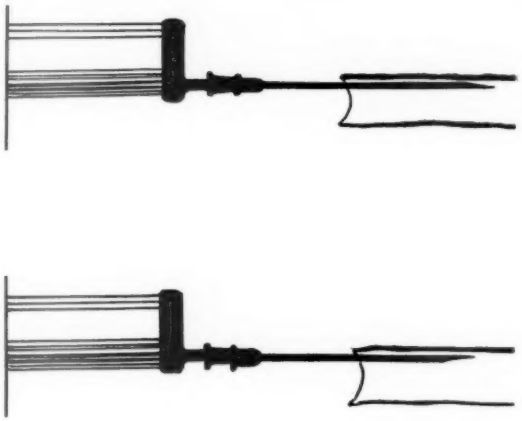

FIG. 1.

"ride up" as is a good precaution, the contents of the syringe will still enter the vein instead of being occluded by the anterior vein wall if the bevel is uppermost. The dangers and treatment of perivenous injection should naturally be impressed on them.

It is often said that anæsthetics for major operations are unsuitable ones for training students. My own view is that there are very few operations indeed where the student cannot be taught something if the anæsthetist will take the trouble. A physician who is a good teacher can cover a large part of medicine on a single case of diabetes or cerebral hæmorrhage, and there are many comparable ways in which the anæsthetist can also teach if he wants to:

(i) How to give an intravenous injection.

(ii) What premedication the patient has received, with the doses. (It is remarkable how few students ever look at the prescription chart or know what drugs their patients are receiving.)

(iii) How to take and keep a record of the pulse and blood pressure—to give only a few instances which come to mind.

There have been a number of articles written and papers read recently on the subject of medical education. We are all agreed that the content of the present syllabus is grossly overcrowded and that it is impossible for the student to acquire or remember all that is crammed into his years of training. Nevertheless every specialist thinks what he is teaching cannot possibly be cut and the burden increases year by year. I think we must not be too greedy of time in teaching our own specialties; we have a part to play in teaching the fundamentals of medicine.

Professor G. W. Pickering says: "The primary purpose of the undergraduate medical course within the University is to train the student's mind so that he can collect and verify facts concerning health and disease in man, and so that he can form a balanced judgment on issues that affect both individuals and groups."

Anæsthesia as a subject for undergraduates is in fact mainly practical, and it behoves us all to ensure that the simple things we teach them, even if few in number as I think they should be, are well understood.

We have, however, a very definite duty towards the next generation not only to impart the facts of our specialties, but to give them a standard of ethics and that sense of responsibility and membership of a great profession that were handed on to us by our predecessors.

The last few years have brought great changes. We live in an age when recruitment for the profession comes from a pool of talent rather than, as in the past, a pool of privilege, and it must lead to the enrichment of the profession. None the less, a background of privilege could and most frequently did in the past give rise to a sense of responsibility, which we should preserve most jealously for the benefit of all. If we wish to maintain professional standards we must first be quite sure that people realize that these standards exist, and it is the duty of the older members of their profession to reiterate again and again quite explicitly what these ideas and ideals are. For example we have, I think, to make a particular effort to show our students that they must preserve a real sense of individual responsibility for what they do.

If we are to retain our standards as professional people and not merely as civil servants doing a routine job bound by hours, conditions and money, we must preserve our independence of thought and that sense of responsibility which should mark the educated professional man. The anæsthetist is really in a unique position to instil these principles into his students for his dealings with them are mainly as individuals, not as groups. The six years of training which a medical course involves should give us ample time and opportunity to instil into our students those principles which we all wish them to have and we can none of us avoid our responsibilities in this respect. We get our students at the most impressionable age and what our standards are and how we view our responsibilities are inevitably the example they take and follow.

The standards we demand from students are what we shall get. I think perhaps we make a mistake in London and in many of the other Universities, in not making more of a ritual of our qualification as "a doctor with the right to practise". In some Universities the taking of some form of the Hippocratic Oath is made part of their Graduation Ceremony. The words may seem archaic and we perhaps cannot subscribe to it in detail but the spirit of it as a standard of ethics is unchangeable.

Section of Dermatology

President—Louis Forman, M.D., F.R.C.P.

[*October* 18, 1956]

Leg Ulcer and Rheumatoid Arthritis. Three Cases.—F. Ray Bettley, F.R.C.P.

Case I.

History.—A housewife, then aged 28, began to develop rheumatoid arthritis in 1950, two months following an attack of salpingitis which had settled down after treatment with penicillin and sulphonamides. In 1952 she developed a rash on the upper part of the front of her chest, three weeks after starting gold therapy; three weeks later, the rash having subsided, gold injections were re-started and continued for fourteen weeks when they were discontinued owing to the reappearance of the rash. This subsided within two weeks of stopping the injections. In 1954 subcutaneous swellings began to appear on the backs of her elbows. During the period March 1954 to March 1955 she received two courses of bee sting therapy applied to the skin overlying her affected joints. In June 1955 an ulcer began to develop on each ankle and in February 1956 she developed a dry pleurisy lasting one week.

Examination on admission in April 1956 showed her to be thin and crippled with rheumatoid arthritis; many subcutaneous "rheumatoid" nodules were present on the extensor surfaces of her arms and over her scapulæ. There was a clean based ulcer 3 in. by 2¼ in. on the outer side of the left ankle.

The smaller ulcer healed slowly on bed rest and local treatment in seven weeks; the larger ulcer only healed after pinch grafting but twelve weeks later broke down at the same time as a fresh ulcer appeared below the outer side of the left knee.

Investigations.—Urine: a few R.B.C. and W.B.C.; culture sterile. Blood urea 27 mg.%. Urea clearance 50% and 31% of normal. I.V.P. normal. Blood counts showed a persistent hypochromic anæmia. W.B.C. counts normal. Blood for L.E. cells strongly positive. Plasma proteins 7·8 grams%. Albumin 3·5 grams%, globulin 4·3 grams%. Electrophoretic pattern showed a raised gamma and alpha-2 globulin. Blood W.R. negative.

Case II.

History.—A housewife, then aged 51, first developed symptoms of rheumatoid arthritis in 1943. From 1951 to 1954 she was treated with various courses of Butazolidin and gold. In 1953 nodules appeared over her elbows and by early 1955 an ulcer had developed on her left ankle.

Examination on admission in February 1955 showed her to be obese and crippled with rheumatoid arthritis; "rheumatoid" nodules were present on the backs of the arms and hands. An ulcer 4 in. by 2½ in. was present on the outer side of the left ankle and one the size of a shilling on the medial side of the base of the left first toe. Chest X-ray showed an area of segmental collapse at the right base which persisted in spite of active treatment. In May and October she had two attacks of constant lower abdominal pain associated with nausea and vomiting and a temperature of 101° F. on one occasion; apart from slight tenderness no other abnormal findings were made clinically or radiologically. In August she had an attack of loss of consciousness for two minutes. Whilst lying in bed she became cyanosed, there was no clonic phase and she was not incontinent. On recovery she complained of a severe right-sided headache. Heart and C.N.S. subsequently normal, as were the EEG and skull X-ray. No healing at all could be induced in these ulcers in spite of nine months in hospital. Grafting failed as also did local injections of hydrocortisone. Systemic steroid therapy was not given at that time. She was discharged home in December.

In August 1956 the ulcer started to extend and to become more painful. She was readmitted in October for possible systemic steroid treatment. Examination showed little change from the previous findings apart from an increase in the size of the ulcers and one fresh one on the medial side of the right first metacarpophalangeal joint.

Investigations.—Urine: normal. Blood counts showed a constant hypochromic anæmia and leucopenia. Blood for L.E. cells strongly positive on two occasions, and negative on two. A positive finding was not associated with any exacerbation of her condition. Plasma

proteins 7·7 grams%, albumin 3·8 grams%, globulin 3·9 grams%. Electrophoretic stri showed a raised alpha-2 globulin and a slightly raised gamma globulin. W.R. negativ

Addendum.—She began prednisone therapy on 6.10.56, so far with no definite change i the size of the ulcer. A week ago purpuric lesions appeared on her legs. Platelet coun 80,000/c.mm.

Case III.

History.—A man, then aged 45, first developed symptoms of rheumatoid arthritis in 1945. In 1947, nodules were present over the left elbow for six months. At the time he was tol that they were "rheumatoid". Raynaud's phenomenon in the hands and feet began in 1952. In 1953 he had gold dermatitis and in April 1954 an ulcer appeared on the medial side o the right ankle.

Examination on admission in November 1954 showed severe arthritis, dusky erythema and telangiectases at the bases of the finger nails, and a clean based ulcer 1 in. in diameter over the medial side of the right ankle.

The ulcer slowly healed over twelve weeks' treatment in hospital, during which time he received hydrocortisone subcutaneously into the base of the ulcer, 25 mg. twice weekly.

Investigations.—Urine: occasional R.B.C. on admission, subsequent deposits normal. Blood counts normal. Blood for L.E. cells (November 1954) negative; (September 1956) positive. Plasma proteins 6·0 grams%, albumin 3·6 grams%, globulin 2·4 grams%. Electrophoretic pattern showed a raised alpha-2 globulin.

Dr. F. Ray Bettley: I have brought these three cases, which have features in common, as examples of a lesion which I have noticed in the last two years or so—the combination of rheumatoid arthritis with ulceration of the legs or feet. When I asked a rheumatologist about this he was inclined to attribute ulceration to immobility and vascular stasis, but I think this is not an acceptable explanation because the legs do not show any such signs. There are no histories of varicose changes and the legs are not usually œdematous. One of the patients now has a good deal of leg œdema, but she did not have that when the ulcers started. She was resting in bed in the ward for many months and the ulcer slowly enlarged at a time when there was no sign of œdema or of arterial insufficiency.

I am indebted to Dr. W. S. C. Copeman who called my attention to the report by Laine and Vainio (1955) on cases which are evidently of this sort. Laine and Vainio do not mention systemic factors in their cases, but it is most significant that these three patients all have features which we usually regard as those of disseminated lupus erythematosus. I do not wish to make a firm diagnosis of lupus erythematosus in these cases, but rather to indicate that, in addition to chronic arthritis and skin ulceration, there is evidence of profound, if not obvious, systemic upset of the kind that is found in disseminated lupus erythematosus.

Biopsy sections have been examined by Professor R. W. Scarff and Dr. A. C. Thackray, who do not at present wish to draw firm conclusions. In many ways they find the histology compatible with lupus erythematosus but two biopsies showed a palisading of histiocytes more suggestive of rheumatoid arthritis. At all events it seems that the histology confirms that something more than vascular stasis is at work.

REFERENCE

LAINE, V. A., and VAINIO, K. J. (1955) *Acta rheum. scand.*, **1**, 113.

Elephantiasis Nostras.—BRIAN RUSSELL, F.R.C.P.

Miss O. M., aged 43.

History.—1943: Bitten by a puppy on the right side of lower lip. About nine months later a small red swelling appeared at this site. It persisted for a few months. Since 1946: Recurrent attacks of redness and swelling of the right sides of both lips and of the right cheek. In later attacks the swelling extended to the nose, eyelids, forehead and scalp.

1950: Admitted to hospital in a severe attack.

1951: A warty lesion was noted on the under-surface of the right side of the tongue. It was excised. The section revealed tuberculosis of the submucosa.

Physical signs.—Non-pitting œdema of the lower half of the face. Firm, finely nodular and scaly surface of the chin. Macrocheilia. Venous congestion and telangiectasia of cheeks and chin. Vasolability, particularly of lower half of the face. Nasal septum deflected to the left. Right pupil larger than the left; no reaction to light; slow transient reaction to accommodation. Facial redness and swelling increase on excitement; right side of face flushes more but sweats less than left side.

Investigations.—Westergren sedimentation rate: 10 mm. in one hour. Blood: hæmoglobin 92%; white cell count normal; Wassermann reaction negative.

X-rays: Chest: calcified foci in right first interspace and right hilum; no active pulmonary lesion. Cervical spine: no bony lesion. Sinuses: mucosal thickening of antra, left more than right.

Bacteriology: Nose—moderate *Staphylococcus pyogenes.* Throat—profuse *Streptococcus hæmolyticus.*

Biopsy from skin of left side of chin: Chronic granulomatous inflammation consistent with tuberculosis or sarcoid. No acid-fast bacilli seen. Several epithelioid cell and giant cell tubercles in dermis, with slight central necrosis and peripheral lymphocytic infiltration. Birefringent particle visible in one giant cell only.

Mantoux reaction: 1 in 1,000 positive.

Past treatments.—Penicillin; Sulphatriad; T.A.B.; superficial X-rays; potassium iodide; ascorbic acid; calciferol (aggravated); isoniazid (115 grams in six months, ineffective); Aureomycin; "tin, gold and iron" from unregistered practitioner; extraction of second right lower premolar for root abscess.

Still's Disease with Recurrent Ulceration of the Legs.—C. M. RIDLEY, M.R.C.P. (for BRIAN RUSSELL, F.R.C.P.)

H. F., aged 14.

History.—This girl first developed painful swellings of the joints at the end of 1948, and the process continued until about two years ago. Since 1949 she has had ulcers on the legs, appearing between October and May and often not healing until well into the summer. She cannot walk, and spends most of her time sitting in a chair. She has never suffered from chilblains.

General health.—Good.

Past history.—Tuberculous gland on right side of neck removed eight years ago.

On examination.—Thin, intelligent girl. Scar on right side of neck. Small glands in axillæ and groins. Typical deformities of rheumatoid arthritis affecting fingers, wrists, elbows, feet, ankles and knees. Marked wasting of limbs. Hands and feet rather cold, but peripheral pulses palpable.

Skin: On the top of the feet and on the calves from just below the knees are some ulcers in various stages of healing and many scars of previous ulceration. The ulcers are round or oval, well defined and shallow, with bluish œdematous edges.

Investigations.—Chest X-ray normal. E.S.R.: 37 mm. in one hour (Westergren). Hæmoglobin 84%, white blood cells 8,200 per c.mm. (polymorphs 68%, eosinophils 1%, lymphocytes 26%, monocytes 5%). Swab from ulcer: *Staph. pyogenes.* Biopsy (ulcer on right big toe): Inflammatory changes with some free iron.

Comment.—It seems probable that the cause of this girl's ulcers is venostasis in an immobile limb with gross wasting of the muscles.

The following cases were also shown:

Subcorneal Pustular Dermatosis.—Dr. I. B. SNEDDON.

Pseudoxanthoma Elasticum (Giant Cell Reaction Nodules).—Dr. ROBERT WARIN.

(1) **Arthropathic Psoriasis.** (2) **Widespread Morphœa.**—Dr. R. H. MEARA.

Dyselastosis with Cysts and Comedones.—Dr. J. H. ALLISON (for Dr. F. RAY BETTLEY).

Incontinentia Pigmenti in a Baby of 12 Days.—Dr. G. A. BECK.

Bullous Urticaria Pigmentosa in a Baby of 2 Months.—Dr. N. A. THORNE.

Nodular Eruption of Back.—Dr. HAROLD WILSON.

Xeroderma Pigmentosum.—Dr. D. L. REES (for Dr. H. J. WALLACE).

Maculo-anæsthetic Leprosy.—Dr. DAVID ERSKINE.

Congenital Poikiloderma (Thomson).—Dr. J. G. COWLEY (for Dr. F. RAY BETTLEY).

Diagnostic Procedures in Bone Disease [*Abridged*]

By T. Russell Fraser, M.D., F.R.C.P., D.P.M.

(*Department of Medicine, Postgraduate Medical School of London*)

Metabolic bone disease is characteristically generalized as distinct from localized or invasive bone disease. But invasive bone disease, for example myeloma, may become widespread and so simulate a generalized or metabolic disease of bone; and on the other hand osteoporosis, a metabolic disease of bone, may predominantly affect the axial skeleton.

Much of the metabolic disorder of bone can be revealed from the metabolism of calcium and phosphorus; but in the future the metabolism of bone matrix may also provide diagnostic tools. Bone is constantly being deposited, remodelled and resorbed. Body fluids often reflect abnormalities of these processes; more direct measures of the rates of bone deposition give more sensitive reflections of bone metabolism.

The important metabolic bone disorders are those which cause thinning of bone and it is with the diagnosis of these disorders which we shall be concerned: (i) That due to excessive bone resorption, which is typically reflected in hypercalcæmia with hypercalciuria and high serum alkaline phosphatase; low serum phosphate may reflect that hyperparathyroidism is the cause. (ii) That due to defective calcification or rickets or osteomalacia, which is typically reflected in the "low calcifiability serum", i.e. one showing a low calcium x phosphate product along with the probably compensatory high serum alkaline phosphatase. (iii) Insufficient bone formation or osteoporosis, or bone atrophy with which we find normal serum levels of Ca and P and phosphatase.

(i) The Recognition of Excessive Bone Resorption due to Hyperparathyroidism

Gley recognized in 1890 that parathyroidectomy leads to tetany, and in 1909 McCallum and Voegtlin showed its association with low serum calcium and its relief by injected calcium. Following this, Erdheim in Vienna was led to study the parathyroids in cases of bone disease —and so to his discovery of the enlarged parathyroids in osteomalacia, which he correctly regarded as secondary. Later, however, thin bones with osteitis fibrosa were also found in his department to be associated with single parathyroid tumours which were clearly not of secondary origin. And so in 1926 a famous Viennese tram conductor, Albert, who had suffered many pathological fractures, was finally operated upon by Mandel and the offending parathyroid tumour was removed.

This pathological approach to hyperparathyroidism has its present-day counterpart in the recognition of hyperparathyroidism either by X-ray or by bone biopsy, i.e. in its recognition from signs of excessive bone resorption. But unfortunately, the typical pathology is only found in the severer instances of this bone disease. In these cases the excessive bone resorption can usually be recognized from X-rays of hands, where it is shown as subperiosteal erosion. This finding is also seen in uræmic osteodystrophy (secondary hyperparathyroidism) and so is not a hallmark of primary hyperparathyroidism. For this distinction we must

turn to the biochemical approach; as also for the recognition of those cases with less gross bone disease.

Concurrently with these new Viennese pathological approaches to hyperparathyroidism, studies were being made on the calcium metabolism of similar cases in the U.S.A. In 1930, from a blood sample showing hypercalcæmia, Dubois diagnosed hyperparathyroidism in another famous patient with pathological fractures, Captain Martell. Since then, the physicians Aub, Bauer and Albright and others, have studied many patients and defined the biochemical criteria for the diagnosis of hyperparathyroidism, based on the estimation of calcium and phosphorus and phosphatase in serum and urine. These procedures disclose parathyroid tumours not only among patients with bone disease, but even more among patients with renal stones and no bone disease.

In hyperparathyroidism with bone disease but without uræmia, these biochemical findings are typical—the raised serum and urinary calcium, associated with a raised serum alkaline phosphatase and a low serum P. However, only sera with at least two of these abnormalities are diagnostic, i.e. the associated phosphate disorders give the clue. But some cases of hyperparathyroidism do not have bone disease and so have a normal phosphatase, and some others have complicating uræmia so that their serum P is no longer low; fortunately either one or other of these phosphate abnormalities is present in the vast majority. Further, it has emerged over the last decade that several conditions may simulate these biochemical findings of hyperparathyroidism—but not both the Ca and P abnormalities. (*a*) A similar hypercalcæmia may occur in bone invasive disease such as myeloma or secondary carcinomatous involvement of bone; and also in some cases of sarcoidosis and in vitamin D poisoning. (*b*) With chronic uræmia, secondary bone disease compounded of various abnormalities (uræmic osteodystrophy) may occur; usually the absence of hypercalcæmia or hypercalciuria can exclude primary hyperparathyroidism or indeed any cause other than the uræmia. Evidence for these conditions should always be sought in atypical cases. In secondary hyperparathyroidism the serum biochemistry will also reveal signs of the basic cause, i.e. of the uræmia or of the osteomalacia.

An assay of serum or urinary parathormone levels will obviously be a useful diagnostic tool in these atypical cases. At Hammersmith, Davies (1957) has shown that this is possible, on forty-eight-hour urine collections, using a benzoic acid extraction and a mouse-phosphaturia assay procedure.

We have noted that the diagnosis of primary parathyroid overaction is usually clinched by finding abnormal P metabolism in association with hypercalcæmia. It is sometimes useful to exclude the suspicion of hyperparathyroidism by assessing both the serum level and the renal excretion of P. Primary and secondary hyperparathyroidism and also several other conditions, including renal disease and Cushing's syndrome are characterized by a high urinary P excretion. The urinary P excretion can only be assessed in the light of both the serum P level and of the renal glomerular filtration rate. If we estimate the ratio of the renal clearance of P to that of creatinine then we can derive a "phosphate excretion index" (Nordin and Fraser, 1956*a*), which will be high in hyperparathyroidism primary or secondary, as well as in the other conditions noted, and low in hypoparathyroidism. This procedure is useful for the recognition of hypoparathyroidism and for the exclusion of hyperparathyroidism—but when high the index does not help distinguish hyperparathyroidism from the conditions which can simulate it.

(ii) The Recognition of Osteomalacia or Rickets

A firm diagnosis requires the demonstration both of the cause of the osteomalacia and also that the serum has a lowered calcifying power. I shall not discuss the ascertainment of the cause, i.e. the assessment of absorption and also of renal tubular function. In the well-developed cases, the radiological findings alone may be diagnostic—revealing the softness of the bones either by deformities or by Milkman's or partial greenstick-like fractures. In the young there will also be seen the widened translucent metaphysis which is hyperplastic but inadequately calcified.

In the typical case, the biochemical criteria of low calcifiability are found in the serum—a low product of the Ca × P concentrations—together with a high phosphatase level indicative of the hyperplastic osteoid. It is usually the P level which is low, but because of the considerable diurnal and dietary variations in serum P levels this abnormality may not always be recognizable from serum levels alone. For the recognition of doubtful or atypical cases, and for the assessment of cases with a known cause such as steatorrhœa but with no clear evidence of bone involvement, we have two further tests available—the calcium infusion test and the bone biopsy. The osteomalacic bones show an abnormal avidity for intravenous infused Ca. If we exclude the vitamin D-resistant cases, which show a urinary leak for Ca, this can be shown by the low 0–12-hour urinary excretion on the test (Nordin and Fraser, 1956*b*). This test can recognize cases before the serum levels are obviously abnormal. If account is also

taken of the rise in serum levels during the infusion, we can also calculate a four-hour bone retention: which is abnormally high in osteomalacia, including the vitamin D-resistant cases.

Further confirmation can be obtained by iliac crest biopsy. For this procedure it is necessary to prepare undecalcified bone sections so that the abnormally wide osteoid seams may be demonstrated. A final confirmation of the diagnosis of osteomalacia is best obtained by the demonstration of the response to treatment appropriate to the cause discovered—e.g. injected vitamin D in cases of steatorrhœa. If need be in doubtful cases, this may be confirmed by showing the increased retention of calcium by balance studies.

(iii) The Recognition of Osteoporosis

Finally we come to cases with translucent bones without evidence of a primary disorder of Ca metabolism, or of a bone invasive disease. For these cases we reserve the term osteoporosis and the diagnosis at present rests mainly on the exclusion of other disease. It is commonly attributed to defective formation of bone matrix, since what forms is normally calcified; but this basis has not yet been proved or disproved. The radiological diagnosis here consists in the recognition that the bones are abnormally thin. Unfortunately, so much of the "bone density" on an X-ray depends on the soft tissues shadow that variations in body thickness are a large source of error here; and at least about 25% of the body's Ca has to be lost before a recognizable abnormality emerges. There are two tests which may help in the recognition of a metabolic defect in these cases of osteoporosis; the Ca infusion test and the strontium infusion test.

The first test has already been mentioned as useful in the recognition of osteomalacia. The four-hour "bone retention" of Ca on this test tends to be low in osteoporosis (Finlay, Nordin and Fraser, 1956). This first test might be called the early Ca uptake in response to a raised serum Ca level.

In order to observe the bone uptake without raising the serum Ca, we should have to inject a suitable tracer of the Ca atoms and observe their rate of disappearance from the body fluids. For this purpose we have used strontium rather than the possibly dangerous radioactive isotopes and found evidence that it does act as a tracer for Ca in the body. We have given a single intravenous dose of strontium and followed the changing concentrations of strontium in the serum and urine over the subsequent seven days. From this data we have been able to derive the daily uptake of Ca by the bones (Eisenberg, Fraser, Ibbertson and Lowe, 1957).

Interpretation of the curve suggests that there are two main Ca pools in the body. The body-Ca pool, or the exchangeable Ca, comprising not only the Ca in the body fluids but also that on the surface of the bones which appears to exchange freely with the body fluids; and the deeper or deposited bone Ca to which there is a steady deposition and from which there is later a steady resorption. This test measures the size of the first or exchangeable Ca pool—from the extent to which the strontium becomes diluted at the conclusion of mixing. We cannot follow the curves long enough to observe the end of the cycle—the resorption of deposited bone; but the steady rate of strontium disappearance, when corrected for urinary loss, reflects the rate of bone deposition from the exchangeable pool. Abnormal resorption should be revealed on this test by a corresponding abnormality in bone deposition and any imbalance between these processes should be revealed from the Ca balance. Preliminary results show that this dynamic test can more precisely define the disordered Ca metabolism of some bone disorders, than can either estimation of the levels of Ca in the serum and urine or balance studies. Severe thyrotoxicosis shows a depleted Ca pool and a rapid bone turnover; some cases of severe simple osteoporosis show a normal Ca pool but defective bone deposition. Hyperparathyroidism shows both an enlarged exchangeable Ca pool and increased rate of bone turnover.

In conclusion, we see that in severe cases, radiology alone can sometimes define the disorder, and standard biochemical procedures can clinch the diagnosis in these cases. For the diagnosis of hyperparathyroidism or osteomalacia, the estimation of serum and urinary levels of Ca, P and phosphatase can often supply the diagnosis. But hyperparathyroidism without bone disease or with uræmia, may be mimicked by certain other diseases. Infusion tests of Ca and strontium can reveal abnormalities in cases of early osteomalacia and of osteoporosis, though the serum biochemistry may appear normal; these dynamic tests may help to elucidate obscure cases.

Pædiatrics in General Practice

VALEDICTORY ADDRESS

By GEOFFREY BARBER, O.B.E., M.A., M.B.

INTRODUCTION

PÆDIATRICS is not a special branch of medicine. It is the whole of medicine applied to a special age group. The pædiatrician is just as much a general practitioner of medicine as we are, and we tend to meet him more often than other specialists in domiciliary consultations for several reasons. The main one is that nowadays relatively few children's ailments really need to be treated in hospital provided that home conditions are adequate: because conservative treatment with antibiotics, the greatly improved economic way of life of the majority of people, the freedom from financial commitment especially in domiciliary consultations, the telephone, and the improved home nursing services all make home treatment more possible. And there is a greater realization that it is *preferable* to nurse a child at home, both from the point of view of the danger of further infection developing in hospital where many children are brought together, and from the harm that is done to a young child by separation from its mother and its home, especially when under the age of 5. Experience in children's diseases is one of the most important sides of medical education, and there is no branch of medicine in which the general practitioner can be of more help to the consultant. So many of the symptoms and signs in children's illnesses are transient and rapid, and we see the early stages of illness which may change quite appreciably before we ask his advice; as family doctors we also see a great deal of minor illness which clears up without ever getting to him at all.

That is my subject: illnesses which present the doctor with symptoms or signs which may cause considerable anxiety at the time, and which clear up without any treatment or after-effects, or sometimes without any definite diagnosis.

THE ALIMENTARY SYSTEM

Abdominal symptoms in children equal in number all the other presenting symptoms put together. "Pain in the stomach" occurs with the greatest regularity right from birth; when an infant yells it is for the parent and for the doctor to find out the exact site of the pain. Often an intelligent mother will tell you that the pain does appear "to be in his stomach", and it is one of the nicest points in physical examination for a doctor to decide whether the tenseness of the abdomen is due to the pain or to the child's vocal efforts. It is often very difficult to decide, and can only be done by the most patient and gentle holding of the abdomen, trying to dip through the tension of the recti muscles between the baby's cries. I can never tell this when the baby is lying on its back, and I prefer the mother to nurse it up against her body and for me to slide a hand gently over the baby's stomach in that position. Even when we decide that there is no rigidity in between the yells, it does not tell us that the pain is not in that region, but it does reassure us a little that there is no serious inflammatory invasion of the peritoneal cavity.

I was always taught to listen to the abdomen, whether in a child or an adult. Active peristaltic sounds are reassuring; one of the most sinister pictures is the absolutely silent distended abdomen. So-called obstructive sounds are not always very reliable, although they may give one a guide. A very loud yell is a reassuring sign; for I am more impressed by the child that lies and whimpers pathetically when you touch the abdomen, trying at the same time to push your hands away. It is the picture of an ill child. One has to re-examine these children quite frequently, even at intervals of an hour or so before coming to a decision; this is particularly true of intussusception because it is so difficult to diagnose in the early stages.

The baby and the parent are so intimately bound together that one is always dealing with a parent as well as a child: the parent wants a diagnosis, the child wants relief. It is very often easier to give the former than the latter: and it is for this reason that there are so many labels which we pin on to the infant for the parent's satisfaction. It doesn't even need a doctor to say "wind" and I suppose that a child who has to suck too greedily because of his hunger at too small a teat often does finally blow himself up with air and have a certain amount of difficulty in getting rid of it, but in my experience a child brings up wind extremely easily when he has merely swallowed it, and usually produces his eructation with a certain

amount of liquid accompaniment or possetting and with an extraordinary show of pleasur . Painful wind often seems to be accompanied by an abnormal spasm, and I suspect that a mi d degree of pylorospasm is far commoner in infants during the first few months of their li e than is generally supposed, and that some of the pain which follows feeding in apparent y healthy babies has been due to this cause. In some cases I have been delighted at the gre t improvement brought about by an empirical use of Eumydrin.

Before leaving the question of "wind" I should like to say a word about the size of th e holes in teats which are usually supplied to the public. When a baby suckles normally, h e stimulates the unstriated muscles of the milk spaces in the breast, so that if the child is temporarily moved milk is squirted forcibly out. In fact he only has to start sucking move - ments for milk to be literally poured into him. A healthy baby will often get his fill from a healthy mother in a matter of a very few minutes. And yet mothers and nurses have the idea that it is harmful for a child to get his milk too fast from bottles and are alarmed if he chokes. I think he is much more likely to collect wind by having to suck too hard and to take it too slowly. A cold in the nose will upset a baby's feeding because it needs such a little mucus to block his tiny nostrils: and he will feed much more slowly because he has to come up for air and he is bound to swallow some! But with clear nostrils, it is much more likely that air will get into his gullet through sucking at a resistant teat, than that milk will get into his windpipe from too large a hole.

The older child—the child from 4 to 14 who complains of acute abdominal pain which is not the usual "D. and V.", nor due to too many plums or green apples. There is a type of pain which seems to come on for several hours or even days at a time, at intervals of anything from a week to several months: the child appears to be quite distressed, and entirely genuine in his or her complaint: seldom is there vomiting or diarrhœa or a rise in temperature, and the attacks usually subside fairly slowly without giving any clue to the diagnosis.

There are several theories as to the cause. In my young days it was fashionable to call them tabes mesentericus, and the theory was that they were due to acute inflammation of the mesenteric glands. When I was a house surgeon at Paddington Green Children's Hospital, a number of these children were operated upon because the surgeon could not exclude appendicitis. The appendix was completely normal, and occasionally some of the mesenteric glands did in fact appear to be enlarged, but the anæsthetist was a hardened old general practitioner and there was usually a derisive noise from that end of the table.

But if we look at the throat of a child during an attack of abdominal pain, we will often see the early stages of an acute tonsillitis or pharyngitis, which will become established during the next day or two, and make it all too clear that the two are very intimately associated: the tonsils stand sentinel at the entrance to the alimentary canal, so that it is quite possible that an infection which shows itself in its maximal stage at the tonsils and in their glands in due course, can in its stage of invasion extend a good deal farther down the alimentary canal.

The second theory is that it is an allergic manifestation. Where the pain can definitely be related to certain foods, this is certainly an attractive one: eggs, especially duck's eggs, are often more than just indigestible to certain people, and it is interesting to try the empirical use of one of the antihistamines during attacks of abdominal pain in this type.

The third theory is the psychosomatic one. Undoubtedly this is a very strong factor in a great many cases, even if it is not the only one. In our English language we associate emotion with abdominal discomfort: we say "homesick", "lovesick", "sick with apprehension", "sick with joy", "sick with fear", indicating that emotion can cause a spasmodic condition in the bowel. Children are very often secretive about their emotions. They have very little experience of the outside world, and a chance phrase caught from a grown-up can only be translated into an image in their mind from their own experience: the result is that they can have secret apprehensions and fears about the life or health of themselves or their relations which we never dream about, and which in time can certainly cause the type of abdominal crisis which I have described.

And then, of course, there is the time-honoured label of intestinal worms. I believe that it is a very big infestation of threadworms that is needed to cause abdominal symptoms: pruritus ani is caused by them, and sometimes vaginitis, but often the mother will bring a perfectly healthy child along to be wormed simply because she has been scrutinizing his fæces and has found these threadworms. I must admit that I accede to the mother's request, but it is as a treatment for her anxiety rather than the child's ailment.

Constipation.—A conscientious mother will often bring a perfectly healthy child to you saying," Doctor, he hasn't had his bowels open for three days, what shall I do?" Just because she is conscientious, it is very difficult to convince her that this need not necessarily be harmful. With a small baby, a direct stimulus to the rectum is often quite enough to satisfy both mother and infant, and I encourage mothers to use their little finger in a well-soaped rubber finger-stall to stimulate a fæcal evacuation. I think there is a definite place

for a small-sized glycerin suppository, for stimulation from below is to be preferred to an irritating laxative given by the mouth. And yet fæcal retention is by no means uncommon in growing children, especially in school children who often have a very full day, and who will get out of the good habits of the nursery simply because there does not seem to be time to go and have a regular evacuation. It is one of the things which they think can be postponed until absolutely necessary, and it is at school that the habits of constipation are often developed. The advice that I give to these children, and to adults who have gone through this stage of voluntary constipation at school and who have never recaptured the habit of a regular evacuation, is to try to empty the bowel the very first thing in the morning when at any rate the bladder has got to be emptied of necessity. The very presence of the full bladder seems to influence the reflex of defæcation, and the constipated child can so to speak "take his bowel unaware" at this particular time.

One has to be very careful to walk delicately between the two extremes, on the one hand of laissez-faire, and on the other hand of making a child acutely bowel conscious. I think that there is sometimes a place for one of the milder laxatives to be taken regularly each night for a time and just long enough in order to re-establish confidence. And of course the question of proper foods, encouraging the child to take those with a fairly high cellulose residue, along with a reasonable explanation and reassurance, may be all that is needed.

Fæcal incontinence is an interesting condition. Sometimes it is psychological, but it is quite often due to chronic constipation which has resulted in a fæcolith, and I have known several cases where careful bimanual examination with one finger in the rectum and one in the lower abdomen has shown the presence of a soft tumour which moulds itself to the touch, and which has been satisfactorily cleared away with a series of enemas. But the presenting symptom of this condition can be a spurious diarrhœa due to the irritation of the fæcolith, rather than the constipation which one would expect.

The Central Nervous System

The commonest symptom here is headache. I need hardly stress the importance of excluding all the possible causes of headache, for in these days when anterior poliomyelitis is probably the greatest fear of the parent, it is far more common for the general practitioner to see simple cases of headache than in the old days when the parent tended to treat them herself: often all that the anxious mother wants is to be sure that it is not in fact the early stages of that most dreaded of all diseases. Errors of refraction, the eruption of teeth, and mild inflammation of the middle ear will declare themselves if you look for them: but I have been impressed with the frequency of acute headache associated with pharyngitis, often in a child whose tonsils have been removed. I suspect that a sinusitis is much more common than we suppose: for instance, an observant parent brought me a child of just over 2 years saying than an acute headache one day had been followed by a profuse purulent discharge down one nostril, which apparently gave complete relief. At the same time it is difficult to visualize X-raying the sinuses in every child with a headache. I have also observed an acute headache which is associated with a considerable pharyngitis, and which has produced a doubtful picture of encephalitis: lethargy, and unsteadiness in the gait which has not cleared up for a week or two after all fever has subsided and the throat has become clean again. Would the cerebrospinal fluid have shown cells if a lumbar puncture had been done? It is part of the burden that general practitioners carry, that we have to decide how far investigations should be instituted in cases of this type. Nobody likes to have a lumbar puncture done on their own child; there is no very great risk attached to it, but at the same time it is quite a serious diagnostic procedure.

Headache in children has many possible causes. It may be (1) part of the stage of invasion of an acute condition, (2) due to a small undetected local cause (such as those I have mentioned of errors of refraction, eruption of teeth, and mild conditions of the upper respiratory tract), or (3) a symptom which appears and for which we never find a satisfactory cause. It may occur by itself, or it may be associated with an abdominal upset, in which case it is difficult to decide which comes first. So often the cause is psychosomatic. Recurrent "bilious attacks" can be associated with any change from the ordinary humdrum nursery routine, particularly where there is a period of anticipation. It may be getting less common, because in the old-fashioned nursery life was so extremely dull most of the time that the rare treat tended to cause a degree of excitement which our more sophisticated children nowadays would find had to understand.

It is quite common to get cases of migraine with children of school age. Often the main cause is the strain of school life, the approach of examinations combined with the physical competition, and the increasing responsibility in the school. It is an early symptom of stress and it is particularly common in the bright young boy who takes his position in the school seriously, and tries to live up to the promise he has shown. I believe that our educational

system is superior to any other in the world, with a reasonable balance between academi work, physical recreation, and training in responsibility and in self-expression. Freedon for the school child to develop hobbies other than the traditional set games is one of ou greatest achievements since the end of the First World War, but at the same time there i no doubt that school is an extremely exhausting business particularly to the children wh are doing well. In Public Schools, prayers in chapel provide a welcome time of quie relaxation when boys have only to sit looking adequately quiet and attentive, and escap from the continual stress of being chivvied round and expected to do things. They ca even let their minds wander without a sense of guilt and retribution. It is not uncommon to have a boy who really needs twenty-four or forty-eight hours' rest in the sanatorium, no because he is ill, but because the stress of school life has become too much for him: and nine out of ten of these boys first complain merely of headache.

Fits.—In its widest sense, the word "fit" may include anything from a very momentary loss of consciousness to a series of convulsions. If we take a child from birth to the end of adolescence, it is more a rule than an exception that he or she will have suffered at some time from at least one occasion of loss of consciousness. Here again the relationship of the parent to the child is of great importance, for the conscientious parent will often bring a child the very first time such a loss of consciousness has been observed, whereas in other cases the child may have suffered from quite a considerable series of fits before the doctor is consulted. And the question which the family doctor has got to decide is when he shall first allow the word "epilepsy" to be mentioned. For instance, a boy was brought to me at the age of 14 with a story of having had fits in his dormitory on waking up in the morning. He was dazed for a few minutes and that was all. The parents were conscientious and the mother took pains to watch the boy herself in the holidays and saw the same thing. The parents pressed me to send the boy to a consultant, and, with no family history, the consultant was loath to pin the label of epilepsy on the boy, so he had an electroencephalogram done and this showed very doubtful minimum irregularities which could not be said to exclude *petit mal*. The result was that this boy was labelled as a minor epileptic, and on the consultant's advice he was given phenobarbitone for a couple of years. The real crux of the problem arose when he had to sign the declaration for a learner's licence to say that he did not suffer from fits. In view of the two years on phenobarbitone and the possibility of this coming out if he was involved in a motor accident I had to advise him to disclose his history. Although he had been free from fits for a long period without any phenobarbitone, it took two years of very considerable trouble, with visits to several consultants for further electro-encephalograms, before we were able to get the boy finally cleared of the stigma and granted a driving licence. The lesson is plain. In minor border-line cases one should warn the parents that if they raise the question of epilepsy there are certain implications which can be most unfortunate. It means that one must have some yardstick by which to judge and of course here the family history is important. But I like to have two or even three attacks of unconsciousness witnessed by somebody really reliable before I raise the question, then a trial period of control by suitable drugs. If there is a recurrence when the drugs are left off then a positive diagnosis is justified.

And then there is the question of the isolated fainting attack due to anoxia. A rather tired boy of 18 or 20 standing in a crowded smoky room, who feels faint and passes out with a series of clonic convulsions. He often has a short period of mental confusion when he comes round, but I have seen several cases of this nature which have certainly never repeated themselves, and where the wise doctor just waits and sees.

Turning to another problem, how does one distinguish between *chorea* and a *tic?* I find several points helpful. First the history. Although the movements are said to have come on in a moderately short space of time, careful questioning will sometimes elicit an illuminating remark like "of course he has always had a habit of screwing his eyes up, or jerking his hair away, but nothing like so bad as this". A marked tic so often develops from a scarcely noticeable one, whereas with chorea one can say "well, three months ago there was no movement at all". A tic is repetitive, the *same* movement tends to recur, whereas chorea is essentially an intention tremor, so that if one sets a child the task of undressing or writing, chorea will interfere more with the intended movements than a tic will. Observing the child while asleep does not always give one the answer, because the small apparently involuntary movements in sleep are so often the answer to a very small stimulus such as a tickle on the skin or a mild discomfort which causes a change in position. When in doubt it is worth trying a short period of intensive treatment as for chorea, complete bed, sedation and salicylates. A tic is unlikely to improve or may even become more pronounced.

In nearly every condition I have dealt with so far, the mind of the child has been a most important factor. It is here that we can so often help the pædiatrician when we refer a problem to him, for we have the great advantage of continued observation of the child against the background of his home life, and not only does the consultant frequently have

to rely on our description of the actual physical aspect, but we can give him this background, both the heredity and the environment of the child. The parents whom he meets for the first time in his consulting room or hospital are closed books, and yet they are the key to the whole of the child's make-up and outlook on life: and we can provide the consultant with that key by giving a thumb-nail sketch of the home life.

Asthma still remains a most puzzling illness (or rather tendency): with both asthma and enuresis treatment must include equally both parent and child. To my mind one of the most marked features of asthma is the decline in frequency in my part of the world during the last twenty-five years. There used to be quite a regular little group of patients on whom one could rely for several night calls, especially at weekends, and I have always been interested in the pattern of the attacks in the different patients. One young man always had his attacks on Saturday nights, and another one always on Sunday mornings: but I think the most remarkable case was that of a boy at a public school who used to have his attacks with the greatest regularity on Monday mornings when he received a letter from his father. The child's father had been at this school and had been a very successful boy. He had never really grown up so that these early successes remained the great triumphs in his life and he was very disappointed at his son who was not repeating the tradition, as the boy happened to be a singularly negative type. The weekend letters were always full of questions as to how he was getting on and how soon he was going to get into the house XV. The boy's method of protection was an acute attack of asthma, so the housemaster tried the effect of withholding the parent's letter for a day or two and the result completely confirmed our supposition, for the boy's attack was postponed on each occasion until the letter was received.

So often it is over-anxiety and over-protection on the parent's part which contributes in the case of asthma in the child.

Croup is an interesting minor spasmodic condition allied to asthma. I always feel that when a child has an attack of croup it is rather the parting of the ways for the parents of that child: for if they give way to unbridled fear and apprehension then they may easily sow the seeds of asthmatic attacks later on. In the same way I have frequently listened to a child's chest when the child has been hot and breathless and excited and heard a number of rhonchi, I think one should always be extremely careful to avoid the use of the word asthma in any sense until it is necessary to use that label. Miss Fanny Burney says that George III beat "Prinny" when he had attacks of asthma. I will leave it to the psychiatrists to say whether this can be considered as one of the factors which formed his rather distinctive character later on.

Anorexia.—It is so usual for a parent to bring a child because he or she will not eat its food, that I expect most us do say to the parent, "Oh, he's reached that stage, has he?" thereby implying its normality. The more conscientious the parents the worse for the child. Nowadays they often demand an X-ray just to see that there is no mechanical obstruction which is preventing the child from swallowing, or in the case of a ruminator is causing the child to bring back the food, and which it does with such pleasure! Usually the child is young enough for the impression of the X-ray not to be associated with its feeding habits, and so it does little psychological harm: but for an older child I think that it does definitely stress the effect that he is having on his parents, and therefore may harden him in his ways. A child's world is so very small compared with ours, that events which are small to us look very large to them. Time is limitless from their point of view, and the one thing they like is to have a good game with as many players as possible. If they can make a mealtime into a general circus which involves the whole household, so much the better and the greater fun for themselves and hoots to grown-ups who don't appear to enjoy it!

Dr. Wilfrid Sheldon paid tribute to the Address by the Section's retiring President. The opening sentence had pointed out that pædiatrics was general medicine applied to a particular age group, to which the corollary was the necessity for a pædiatrician to have a thorough training in general medicine before branching off into pædiatrics, and thereafter to remain *au fait* with advances in general medicine. The observations which Dr. Barber had made about "wind" and the technical problems of sucklings were so full of common sense that they might well be reprinted and adorn the walls of infant welfare centres.

Although doubts were sometimes expressed about the existence of pylorospasm in infants, there were certainly infants whose clinical story simulated that of pyloric stenosis, and in whom gastric peristalsis might be visible but the typical pyloric tumour could not be palpated. There was usually evidence of feeding errors, especially those associated with either underfeeding or some fault in the technique which gave rise to excessive swallowing of air. While the name pylorospasm aptly described the results it was necessary not to be content with a name, but to determine the underlying causes. The correction of these, combined with a sedative for a few days, would usually bring relief. Dr. Sheldon was rather averse to the empirical use of Eumydrin for these infants, for it could easily lead to the drug being employed in infants suspected of hypertrophic pyloric stenosis before the diagnosis had been firmly established. Most authorities in this country required a palpable pyloric

tumour as the diagnostic criterion, but Eumydrin would maintain the pylorus in such a state of relaxation that palpation of the tumour then became almost impossible, and it was therefore preferable to defer the use of Eumydrin pending an authoritative decision as to the presence or absence of pyloric stenosis.

Within recent years it had become necessary to add hiatus hernia to the list of conditions to be distinguished from pyloric stenosis. The presence of specks of altered blood in the vomited material should be enough to raise suspicion, and lead to the examination of a barium swallow under the X-ray screen, by which hiatus hernia could be identified. In three infants both hiatus hernia and hypertrophic pyloric stenosis had occurred together, but the question of their interdependence remained undecided.

The causal relation between an infection in the throat and abdominal pain was one constantly being brought to the notice of pædiatricians. Another common cause of abdominal pain, or perhaps recurring discomfort would be a better description, met with in the middle years of childhood was chronic indigestion, using this term in a broad sense. The story in these cases usually included a description of the child going deathly white at times, having dark rings under the eyes, and perhaps the tongue being dirty or the breath unpleasant. In some of these children the stools would at times be pale, and yawning or too rapid fatigue might be reported, symptoms which would lead one to suspect that a rich Jersey milk was the cause of the trouble; in other children the story would be of the passage of undigested slimy motions, and then very often the cause would be found to lie in the child's diet having far too much roughage in it.

Dr. Sheldon said that if a child was brought on account of fidgetiness, and in the opening statement the mother named one particular movement, it would almost certainly be found that the child was suffering from a tic, for the movements of chorea were so diverse that no one particular movement stood out as remarkable.

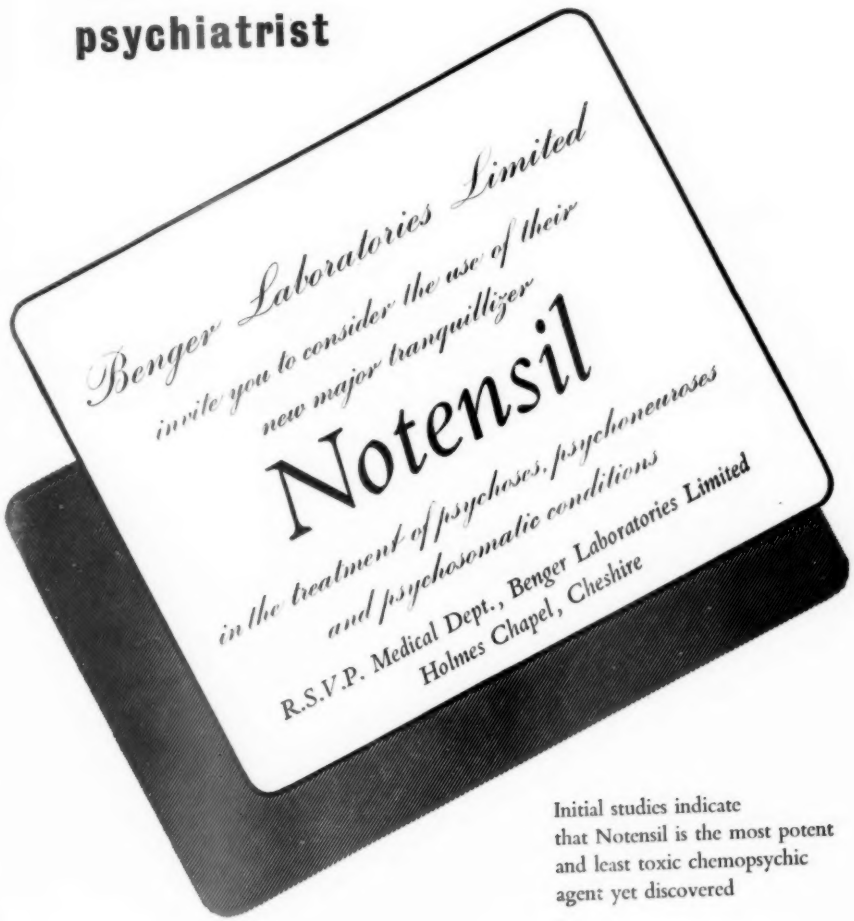
With regard to lack of appetite, especially in young children, the first essential was to record the weight of the child, for sometimes the real situation was that the child would not eat as much as the parents thought it ought to, while in fact they were aiming at too big a target. At all events if the weight was up to or above the average for the age there was obviously no advantage in trying to increase the child's appetite.

Dr. C. B. M. Warren said that one of the pleasant features of the life of a consultant pædiatrician was that much of his work was closely linked with that of the general practitioner. Because children should not go into hospital unnecessarily, pædiatricians had special opportunities for seeing them in their own homes with the family doctor when they were ill with acute but relatively common diseases. Probably in no other specialty did a consultant meet the general practitioner on common ground more often than in this one. How important it was, then, that this pleasant relationship should be preserved.

Dr. Barber had mentioned the child with asthma, an excellent example with which to emphasize the importance of keeping the family doctor in the picture. Sooner or later most children with asthma found their way to hospital. Anxious parents quite reasonably insisted that there should be further investigation. Once the case had been investigated at the hospital, however, and serious disease excluded, the right person to take over the treatment—except in special circumstances—was the general practitioner, who nearly always had an intimate knowledge of the child's social setting and thus was in a better position than the consultant for influencing that to the good. Dr. Warren had never been much in favour of asthma clinics except for purposes of research because he considered that they created the wrong atmosphere for the asthmatic child.

The problem of the child with abdominal pain was common in hospital practice also. For example, a small survey in Colchester had shown that 15% of the children attending the pædiatric outpatient clinic there for the first time had abdominal pain as their main symptom. Sometimes the pain could be related to a minor parenteral infection but more often no cause could be found. Nervous factors, particularly anxiety, must be at the root of the trouble in many cases because it was surprising how often improvement would follow a thorough examination backed up by reassurance of both parents and child.

All convulsions had to be taken seriously and properly investigated; but Dr. Warren agreed with Dr. Barber that a diagnosis of idiopathic epilepsy should not be too readily made, with all that it implied, just because a child had had a single seizure. It might be necessary to take the parents into one's confidence and to tell them what was in one's mind but it was not always necessary to commit oneself to an immediate diagnosis of epilepsy.



Dr. Warren raised the question of the relationship between those running the Welfare and School Clinics and the general practitioners. A fair proportion of all the children attending his outpatient departments were referred directly from these public authority clinics. Not infrequently they were sent to the consultant clinics for relatively trivial complaints which could reasonably have been dealt with by their family doctors. For example, he had had to see young enuretics whose general practitioners had never even been told about their trouble. It seemed to him that those who worked in isolation from the rest of the profession in Welfare Clinics tended to lose touch with clinical medicine, and that it was because of this that they were not always wise in their handling of a situation. He had seen mothers who had been frightened by what had been said to them about the innocent systolic murmur which had been heard over their child's heart at the clinic. His own feeling was that it would be better to have these clinics staffed by practising doctors, that is general practitioners. The problem was not a simple one, however, because although this might, and indeed did, work well in a small town or country practice, it would be much more difficult to organize such a system for the larger towns. He thought that this whole question of the functions and staffing of the Welfare Clinics could be usefully reviewed.

The Changing Epidemiology of Sonne Dysentery [*Abridged*]

PRESIDENT'S ADDRESS

By IAN TAYLOR, M.D., M.R.C.P., D.P.H.

SONNE dysentery is an epidemiological black sheep. At a time when the intestinal infections as a group have come nicely under control, Sonne dysentery has entered a phase of wild and quite uncontrolled epidemicity. So difficult is it to control that many people would be only too glad to ignore it, if that were possible. Some feel that it is a great mistake to dignify this trifling disease by the name of dysentery, which has such a fearful connotation in the public mind. Many of us at some time or another have turned a blind eye in the hope that we would hear no more about it. Sometimes we have been forced into action for fear of what others may say. The present appears to be a suitable time for taking a look at this disease and studying its recent behaviour.

Although it is probable that the causal organism had been described before, the story of this disease really began with Sonne's description in 1915 of the association of the organism with cases of dysentery in Denmark. The Sonne bacillus was reported in Britain from 1924 onwards, and outbreaks in different parts of Britain from about 1930 onwards. Descriptions of early British outbreaks show many of the features familiar to us to-day. Thus MacGill and Downie in 1932 noted the importance of the school as an epidemic centre, stressing that it was particularly the younger school children who were involved. They thought spread was largely due to close contact, and that mild undetected cases were important in spreading infection. About the same time Pickles (1932) was studying his first outbreak, which took place at the time of the year at which Sonne dysentery epidemics occur nowadays.

However, it was a few years later before things began to warm up. Late in 1937 we read in an editorial in the *British Medical Journal* "During the last few months there has been a notable increase in the incidence of dysentery and diarrhœa, chiefly in children. Small outbreaks have been reported from various parts of England and Wales, but the largest increase has been in London . . ." and later in the same article, "Hitherto in this country Sonne dysentery has for the most part remained localized and sporadic in character, in contrast to its epidemic-endemic prevalence in the U.S.A and Scandinavia". It looks as though in 1937 we were seeing the emergence of Sonne dysentery as a widespread epidemic disease in Britain.

Fig. 1 shows the annual notifications of dysentery in the last twenty-five years. The activity in 1937 and 1938, the beginning of which has just been mentioned, was indeed quite notable by previous standards, although almost insignificant in the light of later events. For those who believe that the common infectious diseases are on the way out this diagram will come as a shock. Not only is dysentery being notified at a very much higher rate than ever before, but there is no indication yet that it has reached peak figures.

How many of the notifications are Sonne dysentery? The Public Health Laboratory Service has published each year a summary of all isolations of *Shigella* by type. In 1945 and 1946, 87% were Sonne. In the next two years incidence was low, and the proportion of Flexner dysentery comparatively high, the percentage of Sonne being 57 and 73. The next year, 1949, the figure was up again to 88%, and since 1950 between 95% and 98% of the isolations have been Sonne. It appears that at least the big changes in notification rate are due to changes in the incidence of the Sonne type.

How much are the higher figures due to improved bacteriological facilities? The growth of the Public Health Laboratory Service, and improving techniques in the isolation of the organism are facts, and it would be strange if they were not reflected in a higher rate of diagnosis of dysentery. The setting up of the service at the beginning of the war may have been responsible for a good deal of the increased incidence between 1940 and 1945. It can have had no relation to the decreased incidence immediately after the end of the war, and it is difficult to believe that any changes in organization and technique that have taken place in recent years can explain the enormous increase in notifications in the 1950s. The increase in the last few years probably represents a real increase in the incidence of Sonne dysentery.

How much of the total incidence of dysentery do the notification figures represent? Some years ago Stocks (1949) estimated that notification of dysentery was only fractional.

This then is the first change in the aspect of Sonne dysentery; an increasing incidence durir g the last twenty years consisting of successive waves, each of which has receded less than it ha s advanced, giving the impression of an incoming tide. Whether the tide has yet reached i s highest level we do not know. The years 1947–1949 appear to be worth further study a s possibly containing the reasons why the wartime epidemic ended and the great prevalenc e of the 1950s occurred. During this study we shall find that a number of important change s in the epidemiology of the disease did in fact occur just at that time.

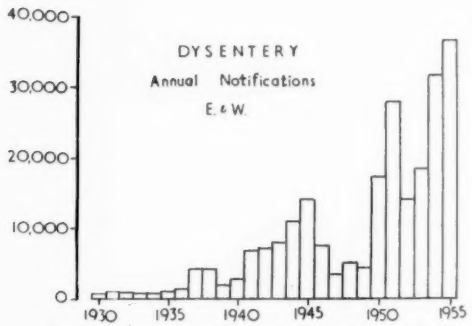

FIG. 1.—Annual notifications in the last 25 years.

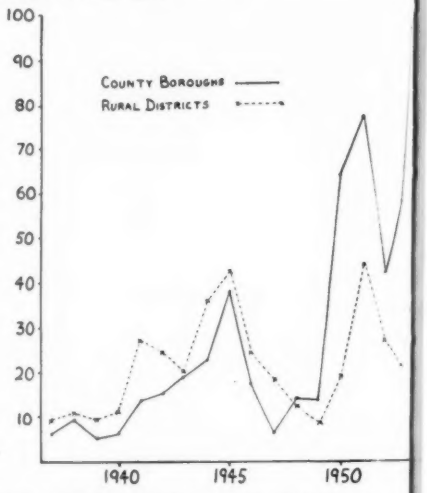

FIG. 2.—Dysentery. England and Wales. 1938–54.→ Notification rates per 100,000 population.

Relation to population density.—During the years in which dysentery has been increasing the experience in the country districts has been quite different from that in the cities. In Fig. 2 the rates for County Boroughs and Rural Districts are shown. It will be seen that up to 1947 the rates in the Rural Districts were higher than those in the County Boroughs, but that thereafter the position was reversed, the disparity between the two types of district being much greater during the last five or six years than before. As far as the Rural Districts are concerned the epidemic of the 1950s has been no greater than the wartime epidemic. It will be noticed that the change-over from rural to urban excess took place during the period of comparatively low incidence after the end of the war. There is no evidence that this change was associated with the wartime evacuation or the return of children to the towns.

The change from rural to urban excess in an infectious disease has been noted before. Greenwood (1935) mentioned it as a change that sometimes happened to a disease when it was in a state of declining incidence, and McFarlan (1951) showed a similar change to be occurring in infective hepatitis in East Anglia in 1946, also during a period of declining incidence. Unlike these examples the change in dysentery occurred during a period of temporary low incidence which was the prelude to the highest incidence ever recorded.

The infectious diseases showing the highest incidence in towns are principally those, such as measles, which spread by personal contact; whereas the most notable example of an infectious disease with a rural excess is enteric fever, a largely food-borne infection. This is a generalization from which there are exceptions. Nevertheless it is suggested that the change from rural to urban excess in Sonne dysentery is consistent with the idea that whereas the disease was at one time spread by a combination of food-borne infection and personal contact, it has now largely abandoned its attempt to be a food infection, and has adopted the far more successful method of personal contact.

Seasonal incidence.—The seasonal incidence of the disease shows equally interesting changes. Fig. 3 gives the maximum notification figure registered in each week of the year from 1947 to 1955. The year's events are shown from nadir to nadir, the diagram running from the 35th week of one year to the 34th week of the next.

In recent years the peak of the dysentery epidemic has been between the 10th and 15th weeks. Following this main peak there is a subsidiary peak about the 20th week. In the curve a peak is also shown about the 50th week, but this is in no way typical and occurred only once during the nine-year period. There is no autumn rise such as is found in enteric fever and food poisoning. This would have been expected between the 36th and the 40th weeks, and such a rise is not seen at all in the dysentery picture from 1947 onwards.

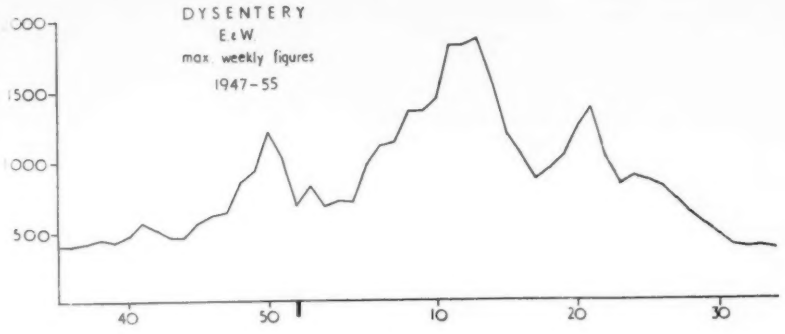

FIG. 3.

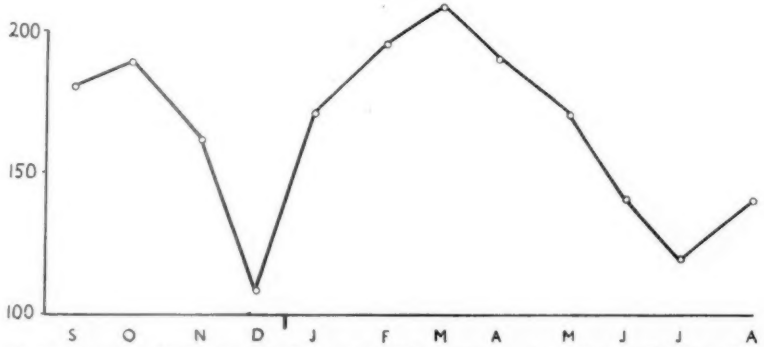

FIG. 4.—Dysentery. England and Wales. Monthly averages of weekly notifications 1941–48. Figures from Glover (1949).

In contrast to this, Fig. 4 is a diagram based on figures published by Glover (1949) for the years 1941 to 1948. Once again the graph begins about the 35th week, but in this diagram monthly averages of weekly notifications are shown. The picture before 1948 was obviously very different from that since that time. The main peak was in March, corresponding to the peak about that time in recent years; but in addition there was, before 1948, a well-marked secondary peak in the autumn, in the months of September and October, at the period of the year in which enteric fever and food poisoning are commonest. The autumn peak, which was present before 1948, has been notably absent in recent years.

This gives further support to the suggestion that the food-borne component has largely disappeared from notified dysentery in recent years. If this is so it is important that it should be generally recognized. Too often do we see the rising figures of dysentery blamed on communal feeding and used unfairly to show how unsatisfactory our food handling methods are.

The idea that dysentery is losing its food-borne component does not rest, however, on indirect evidence only. The figures of reported food outbreaks of dysentery of the Sonne type published by the Ministry of Health and the Public Health Laboratory Service show 41 such outbreaks in the decade 1935 to 1944 compared with only 6 during the period from 1945 to 1954 which was of equal duration but which experienced a very greatly increased incidence of dysentery.

Thus after the year 1947, at which time the incidence of dysentery, particularly Sonne dysentery, was at a low level, the behaviour of the disease has differed in certain respects from that before 1947. It has been more prevalent; it has shown a different relation to population density; it has had a different seasonal incidence; and it has been less associated with food infection than formerly. It is possible that what we have seen is the appearance of a new strain of Sonne dysentery, one that is better adapted to contact infection as a way of life.

Age incidence.—Some years ago Dr. Alison Glover (1947) wrote of dysentery that "the scourge of armies has become the bane of nurseries", pointing out that the disease was largely one of young children. In recent years there have been a number of reports stressing the way in which the disease spreads quickly and widely in families, and it is obvious that an infection of this type cannot remain exclusively in one age group of the population. Davies (1952) reported the examination of 234 home contacts of cases. Half of them became infected, the proportion varying from 37% of the adults, to 50% of the children aged 8 to 15, and about 80% of those under 7 years of age. These findings have been confirmed by other workers, notably Shaw (1953) and Ross (1955).

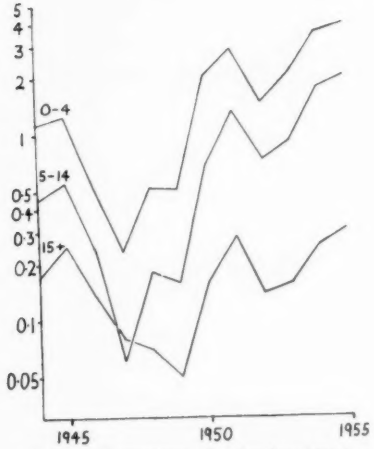

FIG. 5.—Dysentery. England and Wales. Age specific notification rates per 1,000 population.

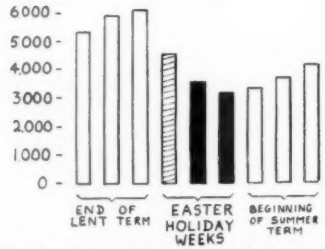

FIG. 6.—Dysentery. England and Wales. Total weekly notifications 1951–55.

It is not surprising, therefore, that a diagram (Fig. 5) of the age specific notification rates over a number of years shows that incidence from year to year has gone roughly parallel in the various age groups. The main exception was in 1947, when for one year the adult rate was higher than that in children of school age. In that year there was a very low incidence of dysentery, coupled with one or two sizable outbreaks of Flexner dysentery in mental hospitals. It is probable that had it not been for the Flexner outbreaks the curve of incidence in the over 15 age group would have shown a dip downwards like those at other ages.

A rise in the percentage of notifications coming in the 5 to 14 years age group in recent years is mainly due to the post-war rise in the birth-rate, but there has also been some degree of closing up between the attack rates in the 0 to 4 years and the 5 to 14 years age groups.

The main focus of activity in Sonne dysentery has now become the primary departments of the schools, where outbreaks are becoming quite frequent.

In view of this association with the schools one would expect to see some evidence of a connexion between the school calendar and the incidence of dysentery. The most constant features of the seasonal curve are the summit of the main peak and the bottom of the trough between that and the following subsidiary peak (Fig. 3). To study the possible relation between these features and the Easter holidays the weekly notifications of dysentery in England and Wales over the five-year period from 1951 to 1955 were taken and arranged not by date, but in relation to the Easter holidays. The dates of the London school holidays were used for this. It is the practice to break up in the middle of a week and to have two and a half weeks' holiday from this time. In Fig. 6 the two black columns are weeks of complete school holiday in London, and the shaded column is half school and half holiday. The height of each column represents the number of weekly notifications in England and Wales.

It is seen that the incidence of dysentery increased steadily during the last three full weeks of the school term; that the beginning of the holiday saw a marked fall in incidence which was maintained through the holiday; and that as soon as the schools reassembled incidence began to rise again towards the secondary peak in the summer term. A somewhat similar picture is seen when figures for individual years are studied. It appears that the main

epidemic is cut short by the break-up of the schools, and that it recovers its momentum when the new term begins. It is not suggested that the schools provide the main impetus for the dysentery epidemic; but there is some evidence that the opening and closing of the schools are responsible for some of the irregularities of the epidemic curve.

Geographical incidence.—When recent incidence in the Registrar-General's Regions is studied we find, in general, a lower incidence in the South and West of the country than elsewhere. This may be due to the tendency already mentioned for incidence to be higher in urban areas than elsewhere.

When comparing one town with another great differences may be due to such causes as variations in the activity of the health department in the search for Sonne, the existence of a public health laboratory in the town, the presence or absence of day nurseries, and many other factors. In most of the large towns there has been a general tendency towards higher incidence in recent years. Nevertheless a high rate in one year has not always meant a high rate for all time. Some of the large cities have managed to get comparatively clear after very high incidence. With regard to the low incidence in the South and West Regions mentioned above it is of interest to note that whereas Plymouth and Portsmouth have both had low rates Cardiff and Bristol have both experienced comparatively high rates. Stoke, Birmingham, and Coventry form a persistent low incidence group in the Midlands which has weathered the storm that has raged about it. It is difficult to find any general rule governing incidence in the large towns in recent years.

The distribution of dysentery in London in recent years has been interesting. Three two-year periods of high incidence were chosen, viz. 1944–45, 1950–51, and 1953–54, and a list was made of the Metropolitan Boroughs in London which had an incidence of more than 1 case per 1,000 population in all three of these periods. Nine Boroughs were in the list. With the exception of Chelsea all the high incidence Boroughs formed a compact block ranging from St. Pancras, Islington, and Stoke Newington in the north, through Finsbury, Shoreditch, Bethnal Green and Stepney further south, to Bermondsey on the south side of the river. The high figures in Chelsea had been inflated by repeated high incidence in a single establishment and a comparatively small population. The compact area in north London was surprising as the distribution of disease and of the various social and environmental factors in London tends to be extremely patchy. The distribution of high dysentery incidence did, however, appear to have some relation to at least one of the environmental indices, namely the average number of persons per room as shown at the Census. With the exception of Chelsea all the high dysentery Boroughs had overcrowding figures (based on persons per room) above the average for the County.

In an inquiry carried out by the Joint Committee of Medical Officers of the London County Council and the Metropolitan Boroughs in 1953 it was found that 16% of the persons notified as dysentery in a year were living in conditions of more than 2 persons per room, the figure for the whole population at the Census being 5·3%. In the same inquiry a higher secondary attack rate in families was found when crowding was present than elsewhere.

Prevention and Control

There are some who think that the prevention of dysentery lies in the washing of hands. Others feel that the disease is uncontrollable. Between these extremes the majority attempt to control the disease with varying degrees of hope and despair, success and failure.

Most will agree that when the disease is present we should do what we can to prevent its spread. Nevertheless this does not mean that we should go on automatically repeating standard procedures regardless of whether they are successful or not. We should consider all our preventive measures in the light of the circumstances of each outbreak, and use only those that have a reasonable expectation of success.

For the present, prevention must, perforce, be limited to the mitigation of local epidemics. There are three main lines of attack on any infectious disease, namely eradication of the reservoir of infection, prevention of transmission of infection, and specific immunization. The prospect of immunization against Sonne dysentery does not look hopeful at present.

The reservoir of infection consists of infected human beings. A great deal of bacteriological examination of contacts is carried out in institutional, nursery, school, and family outbreaks. In bringing to light infected persons who may be in need of treatment this work is obviously valuable; in the prevention of further spread results are uneven, and the reasons for success or failure are not fully understood. The earlier in the outbreak that one begins the better the expectation of success. However, the bacteriological approach is limited by the technical factors involved. Even at the most favourable estimate one cannot expect a bacteriological result until the day after the specimen is taken, and by this time the epidemiological picture may have changed, because Sonne dysentery spreads with such speed. The routine and repeated bacteriological examination of contacts is one of the measures which should be examined with a view to relating the labour involved to the results achieved.

A possible partial solution which deserves further thought is that suggested by Dr. Harry Hawke in a letter to Dr. Bill Brewer, the 25th letter in the Widdicombe file, describing a school epidemic of the Merrygowhimbles (*Lancet*, 1955). He suggested advising the head teacher merely to watch and pray and to see that nobody with diarrhœa cooked or served food; four weeks later he would wish to examine the fæces of the whole school and "smite those *Shigellæ* which linger". This could not be the pattern for all incidents, but on occasions where the initial bacteriological survey discloses that infection has spread wider than expected, farther bacteriological surveys might well be postponed until a time when they can be undertaken more purposefully.

A good deal of the impetus for bacteriological examination of contacts comes from the belief that symptomless excreters are of more importance than cases in the spread of dysentery. There is in fact a certain amount of evidence that the reverse is the case. In the inquiry carried out in London in 1953 to which reference has already been made, it was found that the secondary attack rate in families was considerably smaller when the primary case was a symptomless excreter then when the first case had diarrhœa. Ross (1955) has produced confirmatory evidence on this point.

Once the case or carrier is brought to light the question of putting him out of circulation arises. This often raises the subject of admission to hospital. Easton (1955) has written a strong condemnation of the policy of sending Sonne dysentery patients to isolation hospital, and the more one examines this subject the less justification there appears for using the hospital in this way. Only a very small proportion of cases really require hospital treatment; and removal to hospital can have little effect on the spread of infection. Moreover there are disadvantages in hospital admission, such as expense to the community, the danger of cross infection, and the psychological upset to the child. Unless the home circumstances are totally unsuitable there can be little justification for removal to hospital except in the rare case that must be admitted for treatment that cannot be given at home.

The other form of attack on the reservoir of infection is the direct attack on the organism. It is true that the trials of sulphonamide prophylaxis in day nurseries were not encouraging, but there may be many reasons for this, and this line of attack is surely worth pursuing farther. What is required is a drug that is cheap and effective in quickly and permanently rendering an infected person negative, and which can be given in general practice to sufferers and their family contacts. The disease with which we are dealing is so mild that the drug used must be quite free from side-effects.

The last method of prevention is control of the transmission of infection. The extreme rapidity with which the disease spreads in a closed or semi-closed community makes one wonder whether infection may sometimes be carried by the indirect air-borne route. The organism has occasionally been recovered from dust in the environment of cases. It is not suggested that this is an important method of spread, but we should, perhaps, keep an open mind on the possibility that it may sometimes operate.

If there were ever any doubts about the principal mode of spread of the disease they have surely been abolished by the painstaking demonstration by Hutchinson (1956) of the manner in which children constantly infect their hands from lavatory seats, and the methods by which the seats become infected. This clear demonstration deserves a thorough follow up; a known risk of this kind cannot just be accepted quietly. However, the difficulties should not be underestimated. It is not only a matter of making people wash their hands. The whole subject of the design, method of use, and management of the lavatory is involved. It is a humiliating fact that after 100 years of main drainage the organization of the prevention of lavatory infection, particularly among groups of children, remains one of our biggest problems.

Malignant Carcinoid Tumours

By REGINALD E. B. HUDSON, M.D.

Institute of Cardiology and National Heart Hospital, London

AMONG the lining cells of the mucosa of the intestine and elsewhere there is a very small proportion of yellow cells which have an affinity for silver stain. These cells were first demonstrated by Kulschitzky and are therefore known as Kulschitzky's yellow cells. Later, Masson showed their affinity for silver stain and so they are now called argentaffin cells. They are thought to be the origin of argentaffin tumours. Since 1907, these tumours have been called "carcinoids", but they are better described as argentaffin carcinomas. Though the majority are relatively benign and quite common, a few can become very malignant and it is this type of metastasizing argentaffin carcinoma which, in the past three to four years, has been recognized as being associated occasionally with cardiac lesions in a well-defined syndrome.

The primary tumour and its metastases elaborate an excess of the hormone serotonin (5-hydroxytryptamine), which is carried in the portal and hepatic veins to the heart. When it reaches the lungs, however, the serotonin excess is removed by the lung enzyme, monoamine-oxydase, which converts the serotonin to 5-hydroxy-indole-acetic-acid. This is excreted in the urine and the detection of an excess is therefore used as a screening test for the presence of argentaffin carcinoma.

Only those parts of the heart which have been bathed with large amounts of serotonin show major lesions so it follows that, normally, the chief changes are confined to the right heart, particularly the tricuspid and pulmonary valves.

The characteristic syndrome is that of tricuspid or pulmonary stenosis (or both) in a patient who has the symptoms of flushing attacks, especially after meals, bronchial asthma and diarrhœa.

CASE REPORT

Woman of 33 was admitted to the National Heart Hospital under Dr. Paul Wood for investigation of pulmonary stenosis. It was soon realized that this might be associated with argentaffin carcinoma because she had the typical symptoms, and nodules could be palpated on the liver surface. Catheter studies were made and the findings published by Goble, Hay and Sandler (1955). Sir Russell Brock removed the primary tumour from the ileum and some liver metastases. She then had various treatments including radioactive gold, which relieved the symptoms a little but caused severe neutropenia from which she recovered. The subsequent course, however, was one of pathetic mental and physical deterioration leading to her death two and a half years after the onset of symptoms.

Pathology.—The primary tumour, removed at the Brompton Hospital, was situated in the ileum raising the mucosa into a lump about the size of the thumbnail. Histology proved it to be an argentaffin carcinoma, as did the liver biopsies.

At necropsy, there was much emaciation. The skin incision and end-to-end anastomosis in the ileum were both perfectly healed. The findings are presented in the order of the circulation.

The *liver* was enlarged to 2,200 grams and studded with rounded metastases, some of which were visible on the surface. Several nodules formed a confluent mass in the right lobe. Histologically the appearances were those of argentaffin carcinoma—the cells being arranged in neat masses in direct contact with blood in large sinusoids. The *heart* was not enlarged, weighing 250 grams. The right atrium was normal to the naked eye, but microscopically showed patchy thickening of the endocardium. The tricuspid valve was moderately stenosed and strongly resembled that in chronic rheumatism. The cusps were much thickened and fibrous, adherent at the commissures, and the chordæ tendineæ greatly thickened and shortened (Fig. 1). On section, the cusp thickening was seen

FIG. 1.—Tricuspid valve displayed to show the thick fibrotic cusps and the thick shortened chordæ tendineæ. Note the small warty projection on the endocardium at the junction of papillary muscles about the middle of the left-hand cusp.

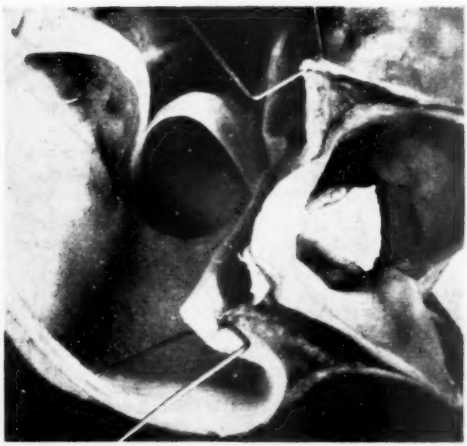

FIG. 2.—Unopened pulmonary valve from above on the right showing triangular stenosed orifice, the thickened shrunken cusps and small sinuses of Valsalva. Aortic valve on left normal apart from some thickening in sinus of Valsalva of upper cusp.

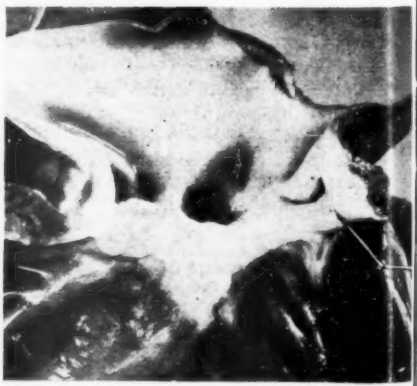

FIG. 3.—Pulmonary valve cut open to show the massive fibrosis involving the cusps and making a "waist" between the pulmonary trunk and the infundibulum. Note the fibrosis extends down into the infundibulum.

to be due to masses of fairly acellular fibrous tissue, without cell reaction or evidence of recent thrombus formation. The right ventricle showed early hypertrophy. The pulmonary valve was even more affected than the tricuspid; the orifice was stenosed to a triangular shape and the cusps greatly shrunken, thickened and hard with fibrosis (Fig. 2). The sinuses of Valsalva were greatly reduced as a consequence of this process, which caused a "waist" between the infundibulum and the pulmonary trunk. There was some spreading of the fibrosis down into the endocardium of the subvalvular infundibulum (Fig. 3). Histologically the appearances were like those of the tricuspid valve—masses of fibrous tissue without cell reaction.

The *lungs* proved to be showered with tiny metastases, the largest being only 1–2 mm. across; one section revealed cancer cells in a lung capillary. In addition, there was early bronchopneumonia.

The *left heart* appearances were practically normal, contrasting strikingly with those of the right heart. There was a little endocardial thickening in the left atrium which was otherwise normal. The mitral valve was normal macroscopically, but microscopy revealed a recent thrombotic lesion on a cusp (Fig. 4). The aortic valve, too, was virtually normal though there was some thickening

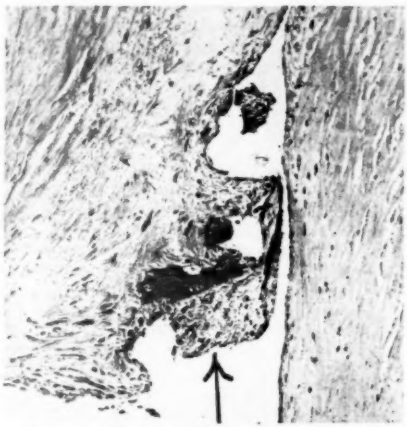

FIG. 4.—Mitral valve cusp. The arrow points to a projecting lesion, probably thrombotic. (Hæmatoxylin and eosin. Low power.)

at the base of one of the cusps. It is feasible that these trivial left heart lesions were associated with the lung metastases, or possibly with an excess of serotonin getting through the lung barrier.

No lesions were found in the brain, kidneys, or in other organs.

DISCUSSION

It seems extraordinary that the description of this new syndrome has lagged half a century behind the first accounts of argentaffin tumours. The condition is undoubtedly rare, and it is possible that in the past any heart lesions found might have been thought to be congenital and not associated with argentaffin carcinoma. Although it has not been shown that serotonin itself is the cause of the cardiac lesions, this is the first disease in which a hormone has been demonstrated to be closely associated with valvular lesions of the heart.

If we are to discover an agent, if such exists, which is associated with predominantly left-sided heart lesions—as in rheumatic fever—it will be found in arterial blood coming from the lungs, and it will exert its major effects on the left atrium and the mitral and aortic valves. Thereafter, it might be removed by the liver and only when it is in such excess as to pass this barrier will it produce sclerotic lesions in the right heart. Such a sequence of events would explain why, in rheumatism, tricuspid and pulmonary valve lesions do not occur in the absence of lesions of the mitral and aortic valves. To my mind, this is the most important aspect of the discoveries associated with the study of argentaffin carcinoma—namely, that such discoveries might lead to advances in our knowledge of the disease process in a far more common disease, rheumatic fever.

Figs. 1, 2, 3 are taken from Goble *et al.* (1956) *British Heart Journal*, by kind permission.

Malignant Carcinoid Tumours

By R. S. Stacey, M.A., M.D.

University Reader in Therapeutics, St. Thomas's Hospital Medical School, London

Twenty-six years ago Sir Maurice Cassidy (1931) showed to the Clinical Section of this Society a patient who suffered from severe flushes, recurrent attacks of watery diarrhœa, pain in the chest and dyspnœa. The flushing was much exaggerated during emotion and during a meal and there were numerous dilated venules of recent origin over the nose and cheeks. The skin of the trunk was mauve coloured but was liable to sudden changes to vermilion. There was a harsh systolic murmur down the left sternal edge and the liver was large, hard and irregular. This was the first published case of a syndrome afterwards described by Biörck *et al.* (1952) who were the first to associate it with a metastasizing carcinoid tumour of the intestine.

Clinical findings.—Attacks of *watery diarrhœa* have been present at some time in nearly all the cases described. Many of these patients have extensive abdominal carcinomatosis and others have had a resection of gut, but this symptom has also been found in cases where the primary in the intestinal wall was quite small and it has persisted after a small local removal. So it seems likely that the diarrhœa may not always be due entirely to mechanical factors.

The Flush

The description I have quoted from Cassidy's account is typical of cases with well-developed symptoms. In others the skin may be normal most of the time; then a flush starts, usually affecting the face first and then sometimes spreading to the neck, chest and limbs. It may be indistinguishable from a menopausal flush. The colour is usually rather a dusky red but may be cyanotic; or bright red areas may be mingled with areas of cyanosis or even of pallor. In Cassidy's case, flushes were precipitated by a heavy meal and this has been noticed in subsequent cases though not all. Two patients shown me by Dr. P. J. D. Snow in Manchester had noticed that half a pint of beer would cause an attack and in one of them as little as 10 ml. 10% alcohol could be relied on to bring it on. In another case, in which emotion precipitated flushing, a few micrograms of noradrenaline injected intravenously was effective. As time goes on the flushes may become more and more severe, last longer and finally the skin may take on a permanent dusky colour, become coarse in appearance and show the dilated venules described by Cassidy.

During a flush the blood pressure usually remains normal, but may fall and the pulse-rate is often increased; sometimes there is abdominal colic or evacuation of the bowels or bladder and sometimes there is an attack of dyspnœa in which there may be signs of bronchospasm. That is to say the flushes may be accompanied by evidence of plain muscle contraction in various parts of the body.

Dyspnœa due to cardiac failure and associated with ascites and œdema is seen in cases with damage to the right side of the heart. This is one of the most remarkable features of the condition and has already been described by Dr. Hudson. Finally in nearly all the cases in which general symptoms have been present, the liver has been large and hard due to metastases.

Widespread, apparently unrelated symptoms such as these might suggest a humoral agent and a lead was given to the search for this by the suggestion made by Erspamer (for references *see* Erspamer, 1954), while working in an entirely different field, that the argentaffin cells of the intestine, from which carcinoid tumours originate, may secrete 5-hydroxytryptamine (5-HT). In 1953 Lembeck estimated the amount of this substance in a carcinoid tumour and found a very high concentration. In 4 patients (Table I) from whom I have had material

Table I.—5-HT in Carcinoid Tumours
(amount found per gram wet tissue)

Case	Primary	Secondary
II	—	0·6 mg.
III	0·3 μg.	0·08 μg.
IV	0·8 mg.	0·7 mg.
V	—	1·1 mg.

the amount of 5-HT in the tumour tissue fell between 0·6 and 1·1 mg. 5-HT/gram wet tissue in 3 of them. In one, which on other grounds was certainly a case of malignant carcinoid, less than 1 μg. 5-HT/gram wet tissue was found in both primary and secondary; this is no more than is found in normal intestine.

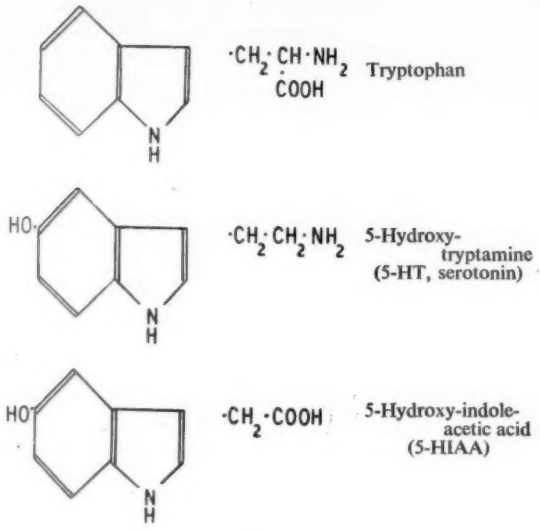

FIG. 1.

5-HT is formed in the body from the essential amino acid tryptophan (Fig. 1) and is subsequently partly oxidized to 5-hydroxy-indole-acetic-acid (5-HIAA), which is excreted in the urine. Normally the urine contains about 6 mg. 5-HIAA per day but in cases of malignant carcinoid this is increased at the very least five or ten times (that is to 30 to 60 mg. per day) and may rise as high as a gram or more per day. Animal experiments show that only about one-third of injected 5-HT can be accounted for as 5-HIAA. What happens to the rest is not known but it is probably safe to assume that 5-HT production is about two to three times that indicated by the 5-HIAA excretion. The detection and estimation of the large amounts of 5-HIAA found in patients with malignant carcinoid tumours is simple and this provides the easiest laboratory method of confirming the diagnosis. There is at present no other condition known in which a large increase in the excretion of 5-HIAA takes place and the finding of this therefore constitutes proof of the presence of a malignant carcinoid tumour.

5-HIAA combines with Ehrlich's aldehyde reagent to give a blue colour and this has been used as a test, but the test described by Sjoerdsma *et al.* (1955) is more satisfactory and can be done in a few minutes. It depends on coupling 5-HIAA with α-nitroso-β-naphthol to give a purple-coloured substance. When applied as described by the authors the test is negative when normal amounts of 5-HIAA are present.

More precise information as to the amount of 5-HIAA excreted may be obtained by the quantitative method of Udenfriend *et al.* (1955) or the shorter method of Macfarlane *et al.* (1956) both of which depend on the reaction mentioned above, or by paper chromatography (Curzon, 1955; Hanson and Serin, 1955; Jepson, 1955).

Amounts of 5-HT found in the blood and urine. Normally 5-HT in the blood is contained entirely in the platelets. Platelets have a great affinity for it and will absorb up to five times as much as they normally contain (Hardisty and Stacey, 1955). This is, no doubt, one reason why there is virtually no free 5-HT in plasma. But a more important reason is that any free 5-HT is oxidized by enzymes in lung, liver, kidney and other organs. When blood clots the 5-HT in the platelets rapidly escapes and part passes into the serum, where it can be estimated, and part into the red cells, where it is lost. There is therefore considerably less 5-HT in serum than in the blood from which it is derived but serum estimations nevertheless provide a rough guide to the amount of 5-HT in the blood provided the method of preparing the serum is standardized. The blood 5-HT and the urine 5-HIAA excretion of 5 cases of malignant carcinoid are shown in Table II. In all both were increased but whereas the average blood 5-HT was only increased eight times the normal, an expression no doubt of the limited capacity of platelets to carry 5-HT, the average 5-HIAA excretion was nearly eighty times that of the normal.

TABLE II.—BLOOD 5-HT AND URINE 5-HIAA IN 40 NORMAL SUBJECTS AND IN 5 PATIENTS WITH MALIGNANT CARCINOID TUMOURS

	Blood 5-HT. μg./ml.	Urine 5-HIAA mg./gram creatinine
Normal: mean ± S.D. (Snow *et al.*, 1955)	0·16 ± 0·06	3·6 ± 1·3
Carcinoid: mean	1·15	280
range	0·4–2·2	22–1,230
Carcinoid/Normal	8	78

Both on account of ease of estimation and the greater abnormalities found, urinary 5-HIAA estimation is the estimation to be preferred to establish a diagnosis.

The urine normally contains only traces of 5-HT and Table III shows the amounts found

TABLE III.—5-HT AND 5-HIAA IN URINE

Case	μg. 5-HT/ml.	μg. 5-HIAA/ml.
I	0·65	70–400
II	0·4	100–2,000
III	20	7–44
VI	0·6	100
Normal	0·01–0·7	1–5

(Lembeck and Neuhold, 1955)

in 4 cases. In 3 of these the excretion was within normal limits, though all were excreting very large amounts of 5-HIAA; in one it was high and this has been verified on numerous occasions.

We have, then, clear evidence that large amounts of 5-HT are formed by carcinoid tumours and that this reaches the blood stream, is oxidized to 5-HIAA and other substances and is excreted. 5-HT is pharmacologically a most active substance; 5-HIAA is inert. We now come to the question: How far are the symptoms of patients with carcinoid tumours explicable in terms of the known actions of 5-HT?

5-HT contracts plain muscle and infusions in man cause diarrhœa, intestinal colic, evacuation of the bladder and bronchospasm. These are all effects met with from time to time in this condition. Infusions also cause flushing and large doses may cause a patchy cyanosis; here again there is a correspondence between the actions of 5-HT and the symptoms to be explained but exactly how these changes are brought about is not clear. 5-HT is a vasoconstrictor and increases peripheral resistance, but whether the flush is due to the effects of stagnant anoxia on the skin vessels, or to venous constriction or some other mechanism, has not been investigated.

The effects of 5-HT on blood pressure are complex. In man and in experimental animals, a rise, a fall or, more often, a fall followed by a rise may be obtained under different circumstances. Apart from the peripheral constriction I have mentioned, it constricts pulmonary vessels and also tends to cause a reflex fall in blood pressure by stimulation of afferents arising in the heart, pulmonary circulation and carotid bodies. Usually patients with malignant carcinoid have a normal blood pressure but until more is known of the circulatory effects in man it is idle to go into this question in greater detail.

By an action on the chemo-receptors of the carotid body, 5-HT stimulates respiration; and this action may play a part in the attacks of dyspnœa.

The pathogenesis of the cardiac lesions remains at present unexplained. The pouring of 5-HT into the portal and hepatic veins probably leads to high concentrations free in the plasma where normally there is little; and this would be largely removed in the lungs. So that if the changes in the heart are due to the action of 5-HT it would be the right side of the heart which might be expected to be the more affected—as indeed it is. Finally 5-HT has been shown to have an antidiuretic action and, on injection into the 3rd ventricle, striking cerebral effects. No changes in patients have been found which could definitely be attributed to these actions.

Cassidy's description, given here twenty-six years ago, shows that he considered the possibility of one humoral agent, namely histamine being responsible for the flushing, for he describes observations in his patient on the triple response and on the injection of histamine. Recently Waldenström and Pernow announced the finding of large amounts of histamine in the urine and plasma of 3 patients with this condition and offer two interesting suggestions

in explanation. Very high concentrations of 5-HT are known to release the bound histamine of the tissues but whether the concentrations reached in man are sufficient to do this is by no means certain. Their second suggestion is that possibly the same decarboxylase which converts 5-hydroxytryptophan into 5-HT may also convert the amino acid histidine into histamine and that the presumed high concentration of this enzyme in carcinoid tissue may lead to a large production of histamine. This is a matter which can be settled experimentally. In any case it seems that not all patients with malignant carcinoid excrete abnormal amounts of histamine, for of 2 cases I have personally investigated one did and the other did not. The reason for this difference and what effect the presence of large amounts of histamine may have on the symptomatology remains to be determined.

Treatment.—There is, of course, very little that can be done as there are invariably liver secondaries present. Surgical removal of malignant glands has been reported to have been followed by some amelioration of symptoms but surgery carries a definite risk. A severe attack may be precipitated by handling or pressing on malignant tissue and I know of 2 cases in which an attack, ultimately leading to the death of the patient, developed at an early stage in the operation before there was any manipulation of the growth. Temporary improvement has been twice reported after ^{198}Au and deterioration twice after radiotherapy.

Potent antagonists to 5-HT are known but so far they have not shown themselves to be of much value in treating these cases. Bromlysergic acid diethylamide, chlorpromazine and dibenyline would appear to be the most promising for a trial. In view of the precipitation of attacks by excitement and by noradrenaline, the use of adrenaline in treating bronchospasm would seem inadvisable. Finally in cases where large amounts of histamine are excreted it is possible that some amelioration of symptoms might be obtained from antihistamine drugs.

Endomyocardial Fibrosis

By J. Donald Ball, M.R.C.P.

Miners' Chest Diseases Treatment Centre, Llandough Hospital, Penarth

Fibrotic thickening of the endocardium of the ventricles may be seen in myocardial infarction, as a congenital lesion in childhood and sometimes in rheumatic heart disease. In Africa it commonly occurs without any of these associations. In Uganda at least this condition, which has been called by Davies "endomyocardial fibrosis" (1949), is so common that it is one of the three main causes of heart disease, being responsible for 15–20% of all heart failure. (Nephritic hypertension and syphilitic aortitis are the other two.) (Williams *et al.*, 1954.)

This condition has been reported from several regions in Africa. In Sudan (O'Brien, 1954), Northern Rhodesia (Buck, 1954) and Southern Rhodesia (Gelfand, 1954) it is fairly common. A number of cases have been seen in Nigeria (Nwokolo, 1955; Beet, 1954). From this region come the only three examples of the disease in Europeans (Gray, 1951; Edge, 1946). Other reports come from the Gold Coast (Hughes, 1953; Edington, 1954) and Gambia (McFadzean, 1953). In contrast very few examples of the disease have been recorded outside Africa. Only 4 cases in the American literature on obscure heart disease can be accepted as identical (Fienberg and Holzman, 1951; McKusick and Cochran, 1952;

FIG. 1.—*Left ventricle.* Lower half of the ventricular endocardium is greatly thickened. Fibrosis of the inner half of the myocardium at the apex. Ante-mortem thrombus has been cut across at the apex. Mitral valve is not yet affected. (Male aged 65; the main lesion was in right ventricle with massive thrombosis.)

FIG. 2.—*Left ventricle and mitral valve.* Small foc of endocardial fibrosis seen at apex. Posterior cusp mitral valve thickened and completely adherent fibrotic endocardium on upper part of posterior w (Male aged 50; died of pneumonia.)

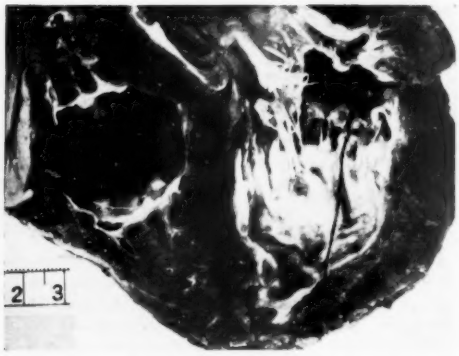

FIG. 3.—*Left and right ventricles.* Left ventricular endocardium almost entirely covered by greatly thickened endocardium. Thin layer of dark thrombus at apex. The right ventricle shows advanced obliteration of the inflow tract. A small crypt lined with thick endocardium marks the site of the old apex. (Male aged 56: died from left and right heart failure of one year's duration.)

FIG. 4.—*Tricuspid valve and right ventricle.* Gross distortion of the valve with marked stenosis. The posterior cusp has completely disappeared beneath a mass of thickened endocardium. The anterior cusp is a short rigid band of fibrous tissue. The ventricle shows advanced obliteration of the inflow tract. (Male aged 30; died after two years in right heart failure.)

Hoffman *et al.*, 1955; Clark *et al.*, 1956). Two of these cases had spent war years in the Pacific islands. A similar number of cases from the European continent are recorded, mostly from Switzerland (Löffler, 1936; Fossel, 1942; Egger, 1944; Brinkman and Prior, 1950). No patient so far has contracted the disease in Great Britain.

Pathology

The heart shows four main lesions (Davies and Ball, 1955):

(1) In the left ventricle, the endocardium of the apex may be greatly thickened and fibrotic (Figs. 1, 2 and 3). It presents a smooth white surface, and may be 1–5 mm. thick. The margins of the fibrotic area are commonly sharply defined. The lesion may spread on to the posterior, lateral and anterior walls but usually spares the septum. The fibrous tissue penetrates the inner third of the myocardium. Ante-mortem thrombus is common on the surface, and calcification in the depths of the lesion.

(2) The mitral valve: The posterior cusp and its chordæ become thickened and eventually bound down to the posterior wall of the ventricle, rendering the valve incompetent (Fig. 2). Mitral stenosis is occasionally seen without any evidence of rheumatic heart disease.

(3) The right ventricular endocardium shows lesions which resemble the left with one exception, the obliteration of the inflow tract of the ventricle. This distortion of the anatomy brings the apex towards the tricuspid valve until the length of the inflow tract is halved (Fig. 3).

(4) The tricuspid valve is involved in a manner similar to the mitral though severe involvement is less frequent. Stenosis is present occasionally (Fig. 4).

Clinical Findings

Patients of both sexes and all ages are liable to the condition (Ball *et al.*, 1954). Our youngest patient was a boy of 4 years. The symptoms and signs depend on the region of the heart predominantly involved. In left-heart lesions the outstanding complaints are the dyspnœa, ascites and œdema of heart failure. If the mitral valve is incompetent a loud, high-pitched systolic murmur and thrill are present at the apex. The heart shows general enlargement radiologically; left atrial enlargement, sometimes with systolic expansion, is present with mitral incompetence.

If right-heart lesions predominate, œdema and ascites are prominent but dyspnœa usually absent. Jugular veins are distended but the signs of tricuspid incompetence—jugular and hepatic systolic pulsation and tricuspid systolic murmur—are usually absent even though necropsy shows gross distortion of the valve to have been present. The explanation for this absence of the signs may be found in the extensive deposits of fibrous tissue on the walls of the right ventricle, which is perhaps thereby prevented from exerting its full systolic thrust. These patients may be very difficult to distinguish from those with constrictive pericarditis; thoracotomy has sometimes had to be performed in the hope of finding a removable lesion.

Ætiology

The cause of the condition remains unknown but certain possibilities demand special consideration:

(1) *Malnutrition.*—Although this was originally suspected in Uganda, recent observations have not confirmed it. Patients are no more malnourished than their fellows. Injections of thiamine produce no response. Vitamin-E deficiency, known to produce myocardial lesions in rabbits (Bragdon and Levine, 1949) and cattle (Gullickson and Calverley, 1946) might be worth investigating.

(2) *Humoral abnormality.*—The lesions in endomyocardial fibrosis are similar in nature to those seen in association with malignant carcinoid tumours. There is some evidence in both conditions that the fibrous endocardium results from organization of deposited fibrin thrombus. Humoral abnormality might therefore be a factor in endomyocardial fibrosis, as in carcinoidosis.

(3) *Sensitization.*—There are also similarities between the mural endocardial fibrosis I have described and the valvular endocardial fibrosis in rheumatic heart disease. This possibility of some pathogenetic relationship is strengthened by the finding of occasional cases which show lesions of both conditions. Though we are ignorant of the cause of rheumatic carditis there is reason to believe that the lesions are associated with sensitization to the products of streptococcal infection. Perhaps a similar mechanism is operating in endomyocardial fibrosis.

Another factor suggesting the possibility of sensitivity is the considerable eosinophilia which has been noted in almost all cases reported outside Africa. Cases in Uganda also show eosinophilia sometimes, but many of these also have helminth lesions, particularly dermal onchocerciasis, which itself causes eosinophilia.

(4) *Virus infection.*—Preliminary reports have described two varieties of virus myocarditis in Africa. One is from Johannesburg (Montgomery *et al.*, 1955) where an outbreak of Coxsackie virus myocarditis was seen in the infants in a maternity home. The other comes from the Belgian Congo, a region in which many of our patients had lived. Here small outbreaks of "encephalo-myocarditis" were thought to be caused by a psittacosis-like virus (Giroud and Jadin, 1955). Little morbid anatomy is available but 1 of the 3 fatal cases did show "l'endocarde . . . épaissi et sclereux". It would seem therefore that there are African viruses which can attack the human heart. Pearce of New York has produced myocarditis in rabbits with several viruses (Pearce, 1950). The resulting acute lesions include endocardial proliferation with obliteration of the crevices. These lesions have not been followed to the chronic stages but allowing for the difference in phase the similarity is remarkable. Other lesions include endo- and myo-cardial fibrosis and calcification. Pearce himself says our lesions resemble his, particularly those of his produced by the myxoma virus.

In conclusion, we do not know the cause, but several pieces of evidence seem to indicate a virus infection.

Other Obscure Heart Diseases in Africa

Novel and mysterious though this condition is, it is only one of a number of obscure varieties of heart disease described recently in different parts of Africa. Apart from the virus myocarditis mentioned there are:

(1) Post-operative mural thrombosis with death from heart failure and embolism described in Dakar by a group of surgeons (Letac *et al.*, 1952-53).

(2) "Nutritional heart disease" with heart failure sometimes responding to a good diet is described in Johannesburg by Gillanders (1951) and Higginson *et al.* (1952). These hearts also show mural thrombi.

(3) "Cardiac collagenosis" is the term used by Becker *et al.* (1953), also in Johannesburg, for a somewhat similar lesion which they believe to be a collagen disease.

(4) "Myocarditis": In Nigeria (Nwokolo, 1955), in South Africa (Higginson, 1952) and in Uganda, patients dying of heart failure are not infrequently found to have cellular infiltration of the myocardium for no apparent reasons. The cells vary, but in some cases eosinophils predominate.

It would seem that for cardiologists as for explorers in other fields, Africa is maintaining her reputation as the source of the new and unexpected.

Primary Amyloidosis

By R. I. S. Bayliss, M.A., M.D., F.R.C.P.
Assistant Physician, Westminster Hospital, London

In surveying this curious condition of primary amyloidosis I have drawn heavily on the excellent reviews by Matthews (1954) and by Symmers (1956)—this last providing an unsurpassed description of the pathological findings.

Classification.—Amyloidosis has been classified into primary and secondary types. As Symmers (1956) has pointed out, however, it is a common misconception that primary amyloidosis implies a particular and unusual distribution of amyloid different from that found in secondary amyloidosis; that the material presents anomalous staining reactions, and that the disease has a characteristic clinical picture. This may be true in some cases but often the distribution and tinctorial reactions of the amyloid tissue may be very similar in the primary and secondary types, so that a pathologist examining histological material without prior knowledge of the case may be unable to predict whether or not the patient had any other precipitating disease. The distinction between primary and secondary amyloidosis resides solely in the fact that secondary amyloidosis is associated with some other disease, presumably important from the ætiological point of view, whereas in the primary type there is no apparent precipitating condition. This distinction is important because correction of the underlying disease may cause a considerable regression in secondary amyloidosis while no effective treatment for the primary type has yet been evolved.

The simplest classification is:

(1) Secondary amyloidosis (associated with some primary disease such as chronic suppuration, rheumatoid arthritis, myelomatosis, Hodgkin's disease, syphilis).

(2) Primary amyloidosis.

(3) Localized amyloid tumours. (These tumours may be localized to the bladder, the upper respiratory tract or the intestines. In some patients an extensive pathological search will reveal clinically silent areas of amyloidosis in other organs and such cases are really examples of systematized primary amyloidosis.)

Pathological findings.—In primary amyloidosis almost any organ of the body may be involved. In the majority, however, there is maximal involvement of the heart and striated muscles, and less striking affection of the liver and other visceral organs. This is in contrast to the findings in most cases of secondary amyloidosis where the brunt of the disease tends to fall on the abdominal viscera. The staining reactions of the amyloid material in both primary and secondary amyloidosis are unpredictable with regard to Congo red and the metachromatic stains such as methyl violet. Although the affinity for Congo red is usually more marked in secondary than primary amyloidosis this is not always so, and often there is a difference from one organ to another. Van Gieson's stain is of value in cases where the amyloid tissue fails to stain with Congo red or methyl violet: the amyloid material takes on a peculiar khaki colour, stands out from the surrounding background and is readily distinguished from hyalinized collagenous tissue.

Clinical manifestations.—The commonest clinical presentation of primary amyloidosis is cardiac failure and this has been the method of presentation in about half the reported cases (Dahlin, 1949; Wollaeger, 1950). Since the average age of patients with primary amyloidosis is 55 years, it is not surprising that the ætiology of the cardiac failure is attributed to hypertensive or ischæmic heart disease. In only a few instances has the correct diagnosis been made *ante mortem* when there have been other features to suggest primary amyloidosis, but the condition should be suspected when there is cardiomegaly without evident cause. The electrocardiogram usually shows low voltage QRS complexes and iso-electric or diphasic T waves in all leads but there is nothing characteristic or specific. The response to digitalization and mercurial diuretics is often poor, and the patient usually dies in a matter of months.

The second most common method of presentation is involvement of striated muscle, and the organ usually affected is the tongue. About a quarter to a third of patients with primary amyloidosis present with macroglossia. The base of the tongue is more involved than the anterior part, and the infiltration may extend, as in one of our recent patients, to the laryngeal and hyoid muscles (Bayliss, 1957).

Involvement of more peripheral muscles is clinically less obvious but may explain the muscular weakness experienced by many patients.

In a quarter of the patients skin lesions occur. The most common manifestations are purpura and small ecchymoses which should be carefully sought for, especially on the eyelids. More specific are amyloid deposits in the skin and subcutaneous tissue. Sometimes the finger pulps are enlarged clinically, but even if they appear normal a biopsy from this site may confirm the diagnosis.

In a small proportion gastro-intestinal symptoms predominate. Thus on three occasions amyloid infiltration of the stomach has led to an erroneous diagnosis of carcinoma ventriculi, and other patients have presented with gastro-intestinal bleeding, and constipation or diarrhœa. Involvement of the liver is more common in secondary amyloidosis, but some patients with the primary type present with hepatomegaly, and develop ascites. Cirrhosis or hepatic metastasis is usually suspected. Tests of liver parenchymal function are normal, and the true diagnosis may be suggested by finding cardiomegaly or involvement of the tongue or by hepatic biopsy.

Other clinical presentations include the nephrotic syndrome, lymph-node enlargement, peripheral neuritis and enlargement of the thyroid. A patient now under the care of Dr. S. P. Meadows at Westminster Hospital presented with a most painful peripheral neuritis, oculomotor pareses, and generalized lymph-node enlargement. The diagnosis was confirmed by biopsy of a lymph gland. Subsequently he has developed hepatomegaly and ascites, and evidence of adrenal insufficiency. Very occasionally a familial history of primary amyloidosis is obtained. Neurologists in Portugal have described families with amyloid peripheral neuropathy, and other familial cases have been recorded in the United States.

Amyloidosis in association with myelomatosis.—About 15% cases of myeloma develop amyloidosis (Bayrd and Bennett, 1950) which may have more of the features usually found in primary rather than secondary amyloidosis and be associated with intra- or extra-osseous amyloid tumours. Occasionally the amyloid material is even found in the cytoplasm of the plasma cells. There does not seem to be any correlation between the development of amyloidosis and the presence of either Bence-Jones proteinuria or hyperglobulinæmia.

Diagnosis.—Confirmation of the diagnosis is best obtained by biopsy. The site for this may be clinically obvious but must in the case of the tongue contain muscle tissue and should be sited as far away from the tip as possible. Where only the heart is clinically involved biopsy of the liver by hepatic puncture or of a finger tip may be rewarding.

The intravenous Congo red test is worth carrying out, particularly if the technique suggested by Fearnley and Lackner (1955) is used, but negative results are often obtained even when there is extensive infiltration.

Prognosis.—The outlook is always bad; death usually from heart failure occurring within two years.

Treatment.—Although there is evidence of reversal of secondary amyloidosis when the ætiological condition is successfully treated, no convincing improvement has been obtained in the primary condition. Claims have been made that large doses of liver extract and massive doses of ascorbic acid cause improvement. The uptake of Congo red may be influenced by these measures, but it is doubtful if the underlying metabolic disturbance is changed. In some cases of macroglossia surgery has been undertaken to make the patient's plight more tolerable. Thus in one case Sir Stanford Cade (Weber *et al.*, 1937) did a successful wedge resection of the tongue but the patient died eight months later of cardiac failure.

BOOK REVIEWS

Diseases of the Liver. Edited by Leon Schiff, M.D., Ph.D. (Pp. xix + 738; illustrated. £5 10s. 0d.) London: Pitman Medical Publishing Co. Ltd. 1956.

This finely-produced book has been written by a team of experts, some of whom work in this country although most are centred in various parts of the United States of America. The foreword points out that the writing of separate sections on one organ by over a score of different authors might well be regarded as ultra-specialism at its most advanced. That this is not so the reader will soon discover when he recognizes how comprehensive is the outlook of most of the contributors, and how the book, although taking a single organ as its main theme, covers a very large part of general medicine.

It is arranged in the well-established manner, beginning with anatomical, physiological and biochemical considerations, and passing on to methods of investigation before describing disorders of function.

All these preliminary sections are excellent, have been clearly written and illustrated by explicit diagrams and some remarkably good photomicrographs.

Emphasis is laid on the experimental method as applied to hepatic disorders, and a section is devoted to experimentally induced hepatic injury, further mention being made of this approach by Sherlock in her section on the liver in congestive failure.

The discussions of disorders of the liver which follow pay full attention to the major problems, and in particular to those of pathology. They cover their respective fields in an up-to-date and authoritative manner, and are, withal, readable. Their value is much increased by the very ample bibliography which is given at the end of each section, reference being made to between 400 and 500 publications in one instance.

A search for minor points or rarer conditions is made easy by the high quality of the index, and is rewarding as the information is there to be found. The hepato-toxic effects of Chlorpromazine are an example of a short, clear account, which is, nevertheless, up to date and full.

This is an attractive book to handle and will prove an invaluable reference book to many, since by elective use the student, the practitioner, consultant or specialist will find, in most instances, that which he is seeking.

Pulmonary Circulation and Respiratory Function. A Symposium held at Queen's College, Dundee. (Pp. xii + 44; illustrated. 12s. 6d.) University of St. Andrews. 1956. (Distributed by E. & S. Livingstone Ltd., Edinburgh and London.)

The Faculty of Medicine of the University of St. Andrews, "conscious of the sad walls that bound the specialties", brought together in Dundee last autumn a distinguished body of people with a common interest in the working of the lungs. The 126 members of this symposium included physiologists, surgeons, physicians, pathologists and at least one obstetrician. No less than one in five of these is the occupant of a University chair, including Professor Liebow of Yale, whose visit as Praelector in Pathology to St. Andrews provided the stimulus for this venture. The proceedings at the two-day meeting are now published in a slim and attractive volume in which the papers given by the twelve principal speakers and the 27 contributions to the discussion are fully reported and illustrated. The book is divided into two parts: "The Pulmonary Circulation in Health and Disease" and "Respiratory Function". There is no doubt that the pulmonary circulation was intended as the main theme of the symposium and the lively discussion of this subject itself justifies the purchase of the book.

The selection of papers in the second part is not as well balanced as in the first. There is a brief general review of respiratory function tests, two papers describing various types of mechanical respirators, one dealing with gas diffusion in the lung and a fifth with pulmonary function in the newborn lamb. The ventilatory aspects of lung function are only briefly discussed and few of the important recent advances in the study of mechanical function are mentioned. The organizers may possibly have felt that accounts of this more specialized work would not have encouraged the broad discussion which was so valuable a feature of the symposium. Those who remember the autumn meeting in Dundee will not be surprised by the fine quality of this publication.

Pathologic Physiology: Mechanisms of Disease. Edited by William A. Sodeman, M.D., F.A.C.P. 2nd edition. (Pp. xxx + 963; illustrated. 91s.) Philadelphia and London: W. B. Saunders Company. 1956.

This is a fascinating book, compiled by 29 American authorities, many of whom are almost as well known in Great Britain as in the U.S.A. The thirty-one different chapters cover all the various systems of the human body, with special chapters relating to such subjects as genetics of abnormal growth and neoplasia, carbohydrate metabolism, water and electrolyte balance, infection and allergy.

The system adopted throughout the book is to give a short account of the anatomy of the part under review, followed by a detailed account of the physiology and histology, with especial reference to such mechanisms as are important to the clinician. Then later in the chapter, or in the chapter immediately following, is an account of the principal clinical states or diseases. Nowhere have we previously found such a composite description of the physiological and pathological mechanisms in diseased conditions.

The book is not one that should be read *in extenso* by an undergraduate medical student, but post-graduates reading for higher degrees and diplomas will find it of great help. It seems unfair to be too critical in relation to a book of this excellence; but we would suggest that the index could be usefully expanded, and the number of diagrams added to by figures illustrating, for example, the electro-cardiographic changes in potassium deficiency. Perhaps also in a future edition the chapter on the central nervous system, and such descriptions as that of electro-encephalography, could be usefully expanded. These criticisms do not, however, greatly detract from what can be regarded as a most useful and well-produced textbook, and the clarity of the print adds to the general enjoyment.

Old Age in the Modern World. Report of the Third Congress of the International Association of Gerontology, London, 1954. (Pp. viii + 647; illustrated. 35s.) Edinburgh and London: E. & S. Livingstone Ltd. 1955.

This report of the Third Congress of the International Association of Gerontology held in London in July 1954 has been published by the British Organising Committee.

Realizing the impossibility of publishing the verbatim report of the Congress the Editorial Committee, entrusted with this task, gave "preference to communications containing original material, opening up new avenues of thought, or presenting authoritative reviews". Other material is given in abridged form or referred to by title only.

For historical record the verbatim report has been deposited with the Library of the Royal Society of Medicine.

The Editorial Committee: Dr. C. Boucher, Dr. O. Olbrich, Mr. W. A. Sanderson, Dr. J. H. Sheldon, Professor R. E. Tunbridge and Dr. Marjory W. Warren, may be truly congratulated on the results of their work. In "Old Age in the Modern World" the reader will find information tackling almost every aspect of the problem of old age, be it administrative, medical or social. From the enormous material of the Congress the Editorial Committee selected the most valuable and original work and assembled this in such a way as to help the reader to find easily the subject in which he is most interested.

The book starts with the speech given at the opening session of the Congress by the Minister of Health, the Rt. Hon. Iain McLeod, M.P. It is followed by the Public Oration delivered by Miss Margery Fry and the Presidential Address by Dr. J. H. Sheldon on "The Social Philosophy of Old Age".

The report itself gives original papers assembled in seventeen chapters dealing with administrative, biochemical, clinical and social aspects of old age in various countries of the world. It gives a good picture of differences in the social structure of populations in other countries and of different methods adopted to deal with the problems of old age. It discusses the results of original surveys on accidents, employment, performance and training in relation to old age.

Throughout the report there is a deep understanding that the aspects of the problem of old age, social and medical, influence each other and cannot be separated. There is also an appreciation that in order to achieve success in dealing with these problems team work is needed and this applies equally whether it be work including planning on a national scale or work in a hospital ward. The fact that old age has its privileges, but has also its responsibilities is constantly referred to. These are some of the common trends flowing through the pages of this book.

It is obvious from the report that more and more people are conscious of the problems of old age and of how they affect every aspect of life.

I consider the report to be a very encouraging one, especially for those who for years now have been engaged in a rather lonely and unspectacular fight for the needs and rights of old people.

Pædiatrics for the Practitioner, Supplement 1956. Under the General Editorship of Wilfric Gaisford, M.D., M.Sc., F.R.C.P., and Reginald Lightwood, M.D., F.R.C.P., D.P.H (Pp. 116 + index 10 pp.; illustrated. 32s. 6d.) London: Butterworth & Co Publishers Ltd. 1956.

This supplement is divided into two parts, the first part containing original articles, and the second part being called a Noter-up.

In the first part there is a chapter that deals with physical changes of puberty and adolescence, and contains a good diagram in relation to the endocrine control of sexual development. Owing to the complexity of the subject and the rapid increase in the biochemical knowledge of the structure of the hormones, the author is unable to lay down a detailed plan for the management of the variations in sexual development around puberty, so that the general practitioner will be forced to send the child to the endocrine clinic when the parents become alarmed.

The chapter on care of children in the tropics is introduced by a good account of advice that can be given to European parents who are going to settle abroad with their children. Then follows an account of the cosmopolitan diseases that may be encountered in the tropics, which includes the bacterial and virus diseases. There is a good account of amœbic dysentery and its complications, followed by an account of trypanosomiasis as it occurs in Africa and South America. This is followed by a complete account of tropical disease as it occurs in childhood.

The general practitioner will find this chapter of great value as a form of reference now that so many coloured children are entering this country from abroad.

The second part of this supplement is headed "Noter-up" and consists of additional information, in relation to the text of the three volumes of Pædiatrics, but it also contains what one would term "corrections" in the light of new knowledge.

I think it would have been better to have placed the additional information under the heading of a supplement, and the small corrections could have come in leaflet form in relation to Volumes I, II and III. On the other hand the Noter-up does keep the three volumes of Pædiatrics well up to date, and as the years go by can be contained in a small volume entitled "Pædiatrics 1957".

The 1956 Supplement is clearly and well written and brings the three volumes of Pædiatrics up to date.

Principles of Biochemistry: an integrated presentation of fundamentals. By A. White, Ph.D., P. Handler, Ph.D., E. L. Smith, Ph.D., and D. Stetten, Jr., M.D., Ph.D. (Pp. vii + 1117; illustrated. £5 12s. 6d.) New York, Toronto and London: McGraw-Hill Book Co., Inc. 1954.

The first thing to say about this work is that it is probably the best advanced textbook of biochemistry at present available. For the postgraduate student who is already specializing in biochemistry, or for the research worker, or for the medical man who wishes to have access to up-to-date information about (shall we say) the aberrant metabolism characteristic of a particular disease—this is assuredly the first volume to consult. Running, as it does, to over eleven hundred pages, it is no doubt a little too deep, and perhaps a little too recondite, for the elementary student of medicine, or for the average practitioner who, unhappily, may not feel himself sufficiently familiar with the complex theoretical bases of modern biochemistry, in thermodynamics, in the electronic theory of valency, or in the niceties of stereoisomerism. But, for those who need a thorough and a scientific treatment, this text may very well form the introductory reading of their choice, before in turn they proceed to even more specialized monographs. The reader can be sure of a critical appraisal of current teaching, and he will find, in some sections, a brief and well-balanced summary of contemporary research. Throughout, primary consideration has been given to the applications of biochemistry in its relations to the mammalian organism, and particularly to man; however, the problems of comparative biochemistry, including microbiology, are by no means excluded.

The "integrated presentation of fundamentals" at which the authors have aimed, although achieved in a remarkably novel way, has certainly been an unqualified success. The procedure that they adopted to write this book was as follows. The first draft of each chapter was assigned to one of the four authors, and when completed was criticized by the other three. Then the four authors met at intervals for discussions of several days' duration; and in some instances the material already written by one author was rewritten by another. Thus, in the end, all four authors had assumed responsibility for, and had in fact contributed to, each chapter. In consequence, the faults not infrequently associated with books written jointly by several authors, such as overlapping and unevenness of style and treatment, are here conspicuous by their absence.

Human Pathology. By Howard T. Karsner, M.D., LL.D. 8th edition. (Pp. xxiv + 960; illustrated. £6.) London: Pitman Medical Publishing Co. Ltd. 1955.

This book has now reached its eighth edition in a period of twenty years and this new volume has been brought thoroughly up to date. It is divided into two parts: part I occupies 380 pages and sets out in simple language the general phenomena of pathology and

the factors which are concerned with it. Part II is termed Systemic Pathology and deals with the various diseases as they affect the different systems of the body.

The contents of the book are well produced and are illustrated by numerous reproductions of specimens and microscopic photographs. It has been brought up to date by the inclusion of much new material—incorporating present-day knowledge on such diverse matters as the blood pigments, the influence of cortisone and ACTH on pathological processes, the stress syndrome, toxoplasmosis and the viruses: and the section on diseases of the liver and of the nervous system have, in particular, been extensively revised. It is helpful to have the pathological phenomena so closely linked in a textbook with the principal clinical features and this to a student of Medicine, whether he be an undergraduate or a postgraduate, is a particularly attractive feature.

Altogether this is one of the best textbooks on pathology now in existence. Added to other attractive features is the excellent way in which the book has been produced and the clear print which makes it easy to read.

The Inquisitive Physician. The Life and Times of George Richards Minot, A.B., M.D. By Francis M. Rackemann, A.B., M.D. (Pp. xi + 288; illustrated. 40s. 0d.) Harvard University Press. London: Cumberlege. 1956.

This is one of the best medical biographies of recent years. Written by his cousin and fellow-student, it tells the story of a distinguished physician and scientific pioneer and at the same time paints a colourful picture of medical Boston in the last fifty years. The author's style is delightful, chatty, and extremely readable, and though the presentation is leisurely, we never lose sight of the principal character of the book. We are introduced to Minot's famous teachers at Harvard Medical School: Walter B. Cannon, the physiologist, Otto Folin, the biochemist, William T. Councilman, the pathologist, Henry A. Christian, the physician, Theobald Smith, the comparative pathologist, J. Homer Wright of "Wright's stain"; at Johns Hopkins where Minot went for postgraduate studies we meet William Sidney Thayer, Alan M. Chesney, and William H. Howell. In 1921 at the age of 35 Minot developed severe diabetes which was treated by Dr. Elliott P. Joslin. Fortunately for the patient and fortunately for all the patients in the world with pernicious anæmia, insulin was then discovered; otherwise Minot would not have lived to make that great contribution with which his name will forever be linked. It was in August 1922 that Banting and Best had sufficient insulin to send a small sample to Joslin. One of the most interesting chapters in the book is naturally devoted to pernicious anæmia (1926), and another chapter tells how the discoverer of liver treatment was awarded the Nobel Prize for Physiology and Medicine in 1934 jointly with William P. Murphy and George H. Whipple. The man behind the scientist is skilfully and sympathetically sketched: Minot bristling with intellectual curiosity; Minot the absent-minded professor; Minot always writing notes whenever he had an idea—"about once every hour or so"—on the edge of an advertisement torn from a magazine; Minot practising the art of courageous living. The book concludes with a genealogy, references, and a good index.

Physical Diagnosis. By Ralph H. Major, M.D., and Mahlon H. Delp, M.D. 5th Edition. (Pp. xi + 358; illustrated. 49s. 0d.) Philadelphia and London: W. B. Saunders Company. 1956.

In the fifth edition of this manual Dr. Ralph H. Major, Professor of Medicine and of the History of Medicine in the University of Kansas, is joined by Dr. Mahlon H. Delp as co-author. The book follows the teaching of the great Skoda that physical signs are produced by physical causes which must be understood before the signs can be properly appreciated. The text is sound and practical, and it is lavishly illustrated by photographs, diagrams, charts, and tables. Some of the illustrations, though well chosen, are not reproduced too clearly, and a few seem unnecessary, but the majority are excellent, and of them it may properly be said that every picture tells a story. It is pleasing to come across a number of original illustrations used by the pioneers in the art of physical diagnosis. Throughout the book there is a delightful historical undercurrent exemplified by numerous "asides" and by the free use of classical descriptions. Priority claims are carefully, but not pedantically, noted. It is regretted that in many cases surnames only are given. In the section on temperature there is no mention of Carl Wunderlich of whom it has been said that he found fever a disease and left it a symptom. Each chapter concludes with a short bibliography, and there is a 30-page index. This fifth edition which has been extensively revised and enriched by many new illustrations, will be found useful and refreshing by the medical student, the practitioner, the teacher, and the consultant. The wealth of pictures makes the price seem moderate.

Transactions of the American Ophthalmological Society 1955. Ninety-First Annual Meeting West Virginia 1955. Being Volume LIII of the Transactions of the Society. Edited by Dr. Gordon M. Bruce. (Pp. xix + 522; illustrated. 144s.) Columbia University Press. London: Cumberlege. 1956.

The 53rd Volume of the "Transactions of the American Ophthalmological Society" presents 19 papers and 3 theses. Some of them are of interest to the physician—blindness following hexamethonium, tuberous sclerosis and retinal findings, periarteritis nodosa and corneo-scleral lesions; some are of interest to the neuro-surgeon—a study of 119 cases of intracranial aneurysm, fibrous dysplasia affecting the periorbital region; but most are specialized and technical. In spite of the spate of literature which has appeared since the war on glaucoma, there are seven papers on various aspects of this disease and its treatment; most of them original in content.

Each paper is followed by a discussion, the opener of which is present by invitation and has read the main paper before the meeting. This makes for informed criticism and facilitates considerably an understanding of the subject. The whole is a tribute to the vitality of American Ophthalmology.

The Royal Northern Hospital 1856–1956. By Eric C. O. Jewesbury, M.A., D.M.Oxon., M.R.C.P. (Pp. xi + 157; illustrated. 17s. 6d.) London: H. K. Lewis & Co. Ltd. 1956.

Seldom can it have happened that "Pygmalion language" plus a slap on the buttocks of an anæsthetized patient has benefited humanity as a whole, and the people of North London in particular. Yet it was undoubtedly the uncouth behaviour of Sherard Freeman Statham, Fellow of the Royal College of Surgeons, which led directly to the foundation of the hospital, now known as the Royal Northern Hospital.

It was also, of course, the inability of the University College Hospital Council to judge Statham's real character which led them to dismiss him from their honorary staff.

Most people now realize that the surgeons of his generation were pioneers in surgery and it was the strain of this pioneer work which made them seem so uncouth, and that they tried to overcome and hide their own nervousness by assuming this blunt manner. Their criticism of the theatre staff and assistants while operating was really self-criticism. The author mentions Lockwood in this connexion, and a story is told of Victor Horsley, who called his theatre sister a " B—— fool" during an operation, met her the next day and, having forgotten the incident, congratulated her on the way everything went.

There was some excuse for these pioneers, but there was no excuse for the next generation, who, without being pioneers, copied the manners of their seniors. All this soon died out and we came to the generation of Barrington Ward, who, as the author mentions, will long be remembered not only for his professional skill but for his great courtesy. If the phrase were not outmoded Barrington Ward could be described as an example of the perfect gentleman.

Much of this history related is a terrible struggle to find money to run the hospital, and Statham spent what little money he had on this great enterprise. When he died of tuberculosis at the age of 32 he left less than £600.

One of the people who did so much for the hospital was Gilbert Panter, secretary for forty-two years. This man just lived for the hospital and on two occasions his services were publicly recognized with special ceremonies, and deservedly so.

In 1948 the hospital was taken over by the National Health Service.

The history of this hospital describes a long struggle for an ideal over a period of one hundred years. The struggle for money is over, but the struggle to give the public the most up-to-date and best treatment and service continues.

This history so brilliantly written by Dr. Jewesbury will interest all those who, like the writer, have had the privilege of serving on the staff of the hospital, and many others; it will also serve as an inspiration to coming generations.

Subarachnoid Hæmorrhage. By John N. Walton, M.D., M.R.C.P. Foreword by Sir Charles Symonds, K.B.E., C.B., D.M., F.R.C.P. (Pp. xv+350; illustrated; 30s. 0d. Edinburgh and London: E. & S. Livingstone Ltd. 1956.

The author is to be congratulated on producing a valuable work of reference upon subarachnoid hæmorrhage, a subject which has become of increasing importance now that the underlying lesions are better known. It is fitting that the foreword should have been written by Sir Charles Symonds who some thirty years ago made a major contribution to our knowledge of subarachnoid hæmorrhage. The clinico-pathological study of this subject is essentially an achievement of modern neurology and is an indication that this discipline is by

no means exhausted and that there yet remain for the alert clinician opportunities of making notable contributions to diagnosis and to treatment.

The monograph is based upon the analysis of 312 particular examples of subarachnoid hæmorrhage together with a review of the extensive literature on the subject. It is well written and arranged, and gives an admirable critical discussion upon treatment. The task of the reader would be made a little easier if every chapter were not infiltrated by figures of a statistical order. Statistics have their necessary place in a work of reference, but it is surely unnecessary that the important sections describing the clinical picture and course and their relation to the several lesions involved should everywhere tell us how many times this and that sign or symptom was present or absent in the total of cases reviewed.

Subject to this minor criticism, the monograph may be strongly recommended as an interesting and comprehensive account of its subject.

Diagnosis and Treatment of Vascular Disorders (Angiology). Ed. by Saul S. Samuels, A.M., M.D., F.A.C.A., F.A.C.C. (Pp. x+622; illustrated. 128s. 0d.) London: Baillière, Tindall and Cox. 1956.

The Chief Editor of this work states that while the blood vessels are considered part of the cardiovascular system our knowledge of them in health and disease has so expanded as to require the entire attention of any single physician or surgeon; in fact he makes a case for separating a specialty of angiology from the comprehensive one of cardiology. Apart from Dr. S. S. Samuels, sixteen other workers contribute to this book which deals with the anatomy and physiology of the peripheral circulation and the diagnosis and treatment of the several diseases that may affect it; three authors write a chapter each from the Department of Surgery in Manchester University, Professor R. H. Goetz of Cape Town University has contributed five chapters, and American workers in this field are responsible for the remaining 16 chapters. Naturally, with such a strong team the book comprises an exhaustive study of the subject, and no one who is specially concerned with the diagnosis and treatment of vascular disorder should be without it although admittedly it is expensive. None the less the price is not too high for a book whose leaves in art paper show so many faultless illustrations, and such authoritative information on a newer section in medicine.

Pott's Paraplegia. By D. Ll. Griffiths, H. J. Seddon and R. Roaf. (Pp. xiv+129; illustrated. 50s.) Oxford University Press. London: Cumberlege. 1956.

Every surgeon or physician who deals with spinal tuberculosis should have this volume on his bookshelf, or preferably on his desk. This monograph reviews the clinical features and pathology of Pott's paraplegia, states the need for operative interference and gives the results of the operations which have been practised. The authors establish their thesis that, in general, operative decompression is the most effective treatment of severe paraplegia, and that in the thoracic region, antero-lateral decompression surpasses other techniques. The results of conservative treatment are critically assessed and found wanting.

Antero-lateral decompression in 50 cases of failed conservative treatment produced 36 successes (the standard of success being either complete neurological recovery beginning immediately after the operation, or recovery of ability to walk well, this recovery commencing during the early post-operative period).

The operation of antero-lateral decompression is so beautifully and clearly described, and made to appear so simple, that the authors are wise to give a final word of advice that its performance should be restricted to experienced spinal surgeons, with intimate knowledge of the conservative treatment of spinal tuberculosis, working in centres fully equipped for the management of the disease and for difficult surgery.

With its 30 plates and 26 diagrams and figures, and with its clarity of exposition, this book is a shining example of how a monograph on any subject should be presented.

The Support of Medical Research. A symposium organized by the Council for International Organizations of Medical Sciences. Edited by Sir Harold Himsworth and J. F. Delafresnaye, C.I.O.M.S. (Pp. xi+170. 17s. 6d.) Oxford: Blackwell Scientific Publications. 1956.

In October 1954 the Council for International Organizations of Medical Sciences (established under the joint auspices of UNESCO and WHO) conducted a symposium "The Support of Medical Research" at the Royal Society of Medicine. This was an historic occasion, for though in the last fifty years central research organizations of medical sciences have been created in a number of countries, their directors had never been given the opportunity of meeting their colleagues collectively and of comparing their experiences. Those who attended this conference will welcome the publication of its report in so pleasant and informal a

volume, to refresh their memories as well as themselves. But anyone interested in medical research should study this report carefully. Its contents include a list of participants; the opening remarks by the chairman, Sir Harold Himsworth; and the report on the conference under the headings: universities and medical research, functions and structure of central research organizations; support of medical research by a central organization; grants; research units and institutes; co-operation between universities and a central research organization; recruitment, training, and support of medical research workers; collaboration in research. Appendices deal with medical research in Australia, New Zealand, Canada, Union of South Africa, Republic of Ireland, India, U.K., U.S.A., Belgium, France, Switzerland, Germany, Netherlands, Scandinavia, Yugoslavia, and Israel. It is significant to note that some countries experience difficulty in recruiting research workers in the pre-clinical fields because of low salaries. The volume concludes with a carefully compiled bibliography (volume numbers of such periodicals as the *British Medical Journal* and the *Lancet* should be given in Roman numerals) and with an index.

Landmarks in the History of Hygiene. By Henry E. Sigerist, M.D., D.Litt., D.Sc., F.R.C.P. (Pp. xii+78; illustrated. 12s. 6d.) Oxford University Press. London: Cumberlege. 1956.

In founding the series of lectures bearing his name and delivered annually at the London School of Hygiene and Tropical Medicine, George Heath Clark emphasized that they should be concerned with the historical, cultural and philosophical aspect of public health. Few are as well fitted to cover these fields as the author of this volume, Dr. Henry Sigerist, the medical historian. Like all his writings, these lectures betray that universality of interests and learning which makes for distinction in a subject where the correlation of different disciplines is basic.

Although some might consider Hippocrates as much the father of hygiene as of clinical medicine, Dr. Sigerist chose Galen as his first subject, pointing out that, as the physician to the Roman court, he was concerned more with the pursuit of personal health by a leisured class than with community hygiene as we understand it to-day. The Regimen Sanitatis of the Salerno school, which reflected this viewpoint, is discussed in some detail. Personal longevity continued to be the aim of the educated laity during the Renaissance and there is a vivacious discussion of the recommendations of Cornaro which were designed to ensure it. His golden rule—to eat just enough "to keep body and soul together"—is receiving fresh backing from recent work on the atherogenic properties of fat in the diet.

With Johann Peter Frank came a change in emphasis. His term for medical officers of health (medizinischen Polizei) has an unpleasant ring to-day but his conception of them as guardians of the community's health was essentially sound. Poverty as a cause of disease and a bar to treatment led to the development of schemes of medical care by, of all apparently unlikely people, Bismarck, and Dr. Sigerist ends his series of lectures with a balanced account of the changing pattern of medical care and some personal thoughts on its future. It is good that these lectures will now reach an audience which may be larger than the original one but is unlikely to be more appreciative.

Radiology of the Alimentary Tract in Infancy. By Roy Astley, M.B., M.R.C.S., D.M.R. (Pp. viii+287; illustrated. 50s.) London: Edward Arnold (Publishers) Ltd. 1956.

The high quality of pædiatric radiological practice at the Children's Hospital in Birmingham has become an established tradition and is widely known. Dr. Roy Astley is to be congratulated on the production of a most valuable book which fully maintains this high tradition. His book is the outcome of exceptional experience and interest in the problems of alimentary disease in infancy and the greater part of the book is clearly based directly on his personal observations.

In a modestly composed preface, the author states that many chapters conclude with illustrative case histories, chosen to emphasize points that have been made in the general text; these are presented in a different type so that for quick reading they may be omitted if desired. This is certainly not a book which merely deserves quick reading: in the reviewer's opinion these case histories are an invaluable feature of the book and should be read thoroughly.

The sections on hypertrophic pyloric stenosis and duodenal obstructions are particularly well done. The general quality of the radiographic illustrations is excellent, especially when it is remembered that co-operation from infant patients is non-existent.

This book should be read by all radiologists and pædiatricians and should be available for quick reference in all radiological departments to which an acutely ill infant may be referred.

Soranus' Gynecology. Translated with an introduction by Owsei Temkin, M.D. (Pp. xix + 258; illustrated. 40s. 0d.) Baltimore: Johns Hopkins Press. London: Cumberlege. 1956.

Soranus, who lived in the early second century A.D., was one of the most learned and critical writers of antiquity. Though the majority of his works have been lost, his most important book, "Gynecology," which exerted considerable influence on many generations both in the East and the West, has been preserved in the original Greek. It is an interesting and historically important document, representing ancient gynæcological and obstetrical practice at its very height, and written apparently for the physician, the midwife, and the educated layman. It has now been translated for the first time into English by Dr. Owsei Temkin, Associate Professor of the History of Medicine at Johns Hopkins University and editor of the *Bulletin of the History of Medicine*, with the help of two obstetricians, Drs. Nicholas J. Eastman and Alan F. Guttmacher, and of a classical scholar, Dr. Ludwig Edelstein. In a fascinating and erudite introduction Dr. Temkin tells the inside story of the translation which was begun some twenty years ago; depicts Soranus as the outstanding representative of the methodist school that derived its knowledge from studying the phenomena of disease; discusses the scope, merits, and weaknesses of the "Gynecology"; and gives an account of the various texts and editions.

The "Gynecology" consists of four books. The first deals with midwives, menstruation, virginity, conception, abortives and contraceptives; the second with parturition and the care of the newborn (a particularly enlightening section); the third discusses various gynæcological conditions (e.g. "hysterical suffocation, "flux of semen" in women), their pathology and treatment, but the author's ideas on the whole strike us to-day as antiquated and vague. The final obstetrical book, on the other hand, is valuable and much more modern. The volume concludes with a list of Ancient Names, Materia Medica (the botanical terms are difficult to identify, especially as Soranus gives no descriptive details), and an Index of Personal Names and Subjects.

Gynæcologists, obstetricians, pædiatricians, and medical historians owe Dr. Temkin a great debt for his labour of love in making this important work available to them in so scholarly and sympathetic a translation which carefully avoids forced interpretations in the light of present-day knowledge, and for his excellent introduction. Their thanks are due also to the Johns Hopkins Press for producing this beautifully printed book—a publication of the Institute of the History of Medicine—which it is a joy to read.

Management of Life-Threatening Poliomyelitis—Copenhagen, 1952–1956. Edited by H. C. A. Lassen, M.D. (Pp. xi+179; illustrated; 22s. 6d.) Edinburgh and London: E. & S. Livingstone Ltd. 1956.

The names of Dr. Lassen and his colleagues became world famous for their magnificent feat of improvisation in the Copenhagen epidemic of 1952. This book is in many ways a history of this epidemic and as such is a most thorough and complete analysis. The statistical tables cover every conceivable feature of the epidemic. Naturally as a textbook it suffers, in some degree, from this historical viewpoint and we might perhaps feel that we had advanced farther in this country. Only Scandinavian machines and methods are described, and of the former we have had somewhat unfortunate experience. There is an attempt to segregate cases into distinct types which we have found seldom applicable. The chapters on basic mechanics of ventilation are quite excellent and indications for tracheotomy are well portrayed. Strangely there is no mention of preliminary "trial" laryngeal intubation. The operation of tracheotomy is well described, but it is not emphasized that a ring of trachea must be left above the stoma. This may account for some space being devoted to the cure of laryngeal stenosis.

The chapters on laboratory procedure are excellent, though perhaps indicating complete reliance on such findings whereas we, apparently, have more faith in clinical judgment.

The discussion of metabolic disturbances in acid-base balance are a little obscure but may have suffered in translation.

In discussing calculus formation it would seem that urinary pH followed a post-prandial pattern, rather than correlation with volume of ventilation, and thus that urinary pH is not a good guide to oxygenation except in extremes of over- or under-ventilation.

This book written on a fast-developing subject is inevitably somewhat behind current practice. It does, however, give a detailed picture of the problem to be faced and contains a mass of information on every aspect of respiratory poliomyelitis. Above all it is a fine record of the achievement of the Copenhagen School when faced with the crisis of 1952.

Cancer Cells. By E. V. Cowdry. (Pp. xvi+677; 137 figs. 112s.) Philadelphia and London: W. B. Saunders Company. 1955.

The purpose of this book, as the author states in the Preface, "is to introduce the reader to the more important facts about cancer cells, to raise questions considered important and, whenever possible, to supply clues as to how he can further explore the issues for himself."

The book develops logically from a definition of cancers in Chapter 1 and a description of the nature of malignant growth in Chapter 2 to consider the cytoplasm and nuclei of normal and malignant cells in Chapters 3 and 4, the chemical properties of cancerous tissues in Chapter 5 and the occurrence of cancers in animals and plants in Chapter 6. In Chapters 7 to 10 the author discusses agents which cause cells to become malignant, and the role of single injury, of viruses and of mutation. Chapters 11 to 13 deal with cellular susceptibility to cancer and with the part played by heredity, by age and by sex. The next three chapters review the subjects of latency and of modifying factors in cancer development and the geographic frequency of different types of cancer. Chapters 17 and 18 deal with prevention, diagnosis and treatment, and Chapter 19 with unexplained disappearance of cancer cells. The last chapter reviews the whole field of cancer research and probable future developments. The book ends with an appendix giving among other things a list of journals, reviews, books, conferences, symposia and reports. There is a very full bibliography of 64 pages and an adequate index of 31 pages.

This is a full and comprehensive review of the cancer problem. As a publication it is first class—the format, the illustrations and the bibliography are excellent. The style of writing abounds in peculiarities of language or sentiment, for example, colloquialisms such as "because the cells have to get along with much less sex hormone than they are accustomed to" (p. 11), "to arrange a marathon between malignant and normal cells, with fairness to both" (p. 30), or "the kick given to susceptible cells" (by cosmic rays—p. 209), or remarks such as "there is of course a reason but it is obscure" (p. 223), or "viruses may be living agents and if so they are biological" (p. 228). Some of the early chapters are rather diffuse and perhaps somewhat too long, but the chapters on the chemical properties of cancerous tissues, on heredity, on modifying factors and on geographic frequency are particularly interesting. The book brings together competently in one volume a mass of information covering many fields of investigation. To do this in a subject which ranges so widely and to do it with up-to-date references is no mean achievement.

Histological Appearances of Tumours. By R. Winston Evans, T.D., B.Sc., M.R.C.S., L.R.C.P. (Pp. xvi + 773; illustrated. 90s. 0d.) Edinburgh and London: E. & S. Livingstone Ltd. 1956.

As with other crafts, skill in surgical histological diagnosis cannot be acquired without prolonged practical experience and in no other branch of clinical pathology is there greater need for close association with a master. Although monographs and atlases on pathological histology undoubtedly have their place and value, they can amplify but never satisfactorily replace such a personal training and the development of the visual memory that it inculcates.

The present volume provides a very full descriptive account of all the common, and many of the less common, human neoplasms with the noteworthy exception of those of the central nervous and female generative systems. As its title indicates, the letterpress is devoted primarily to those morphological considerations that aid the histologist in the identification of a tumour. With some of the more common ones, however, the discussions are more extensive, and attention is also directed to such additional matters as their clinical course, histogenesis, modes of dissemination and sites of metastasis. While much of the book is naturally based on the author's own experience and collection of material at the United Liverpool Hospitals, each section provides a comprehensive survey of current knowledge of some tumour and is supplemented by numerous references to relevant recent articles in British and American literature. It is a pity that more consideration has not been given to the copious Continental contributions in this field of Pathology.

Within its restricted scope, this monograph will serve a useful purpose and will undoubtedly prove helpful to many clinical pathologists called upon to undertake the diagnosis of tumours. The descriptions are clear and detailed, the index unusually full, and the illustrations, including nearly a thousand photomicrographs, for the most part of excellent quality and well reproduced in black and white half-tone blocks. The general production of the book is of a high standard, though it may be questioned whether the binding is sufficiently strong for a heavy volume in frequent demand for reference purposes.

Color Atlas of Oral Pathology. Prepared under the auspices of the U.S. Naval Dental School of the National Naval Medical Center, Bethesda, Maryland. (Pp. xiv + 188; illustrated. £5.) Philadelphia, Montreal: J. B. Lippincott Co. London: Pitman Medical Publishing Co. Ltd. 1956.

This is an excellent book and fulfils most adequately the objects set out in the preface, viz. "To present in concise form the fundamental facts concerning oral disease." It does not aim to be anything other than a book of pictures accompanied by the briefest of texts on the same page as and opposite to the illustration to which it refers. Considerable basic knowledge by the reader is taken for granted and because of this, though not suited for undergraduate students, it makes an excellent book of reference for the postgraduate and practitioner from which the salient facts—clinical, histological and, where necessary, radiological—can be easily ascertained on oral conditions, rare or common, likely to be encountered.

As is inevitable in a book of this type there are a few omissions. For example, the coverage of conditions found solely or mainly in children is extremely poor. Among such conditions of common occurrence—thrush, oral manifestations of the exanthematous fevers and the typical alveolar odontoclastoma (often called an osteoclastoma) which occurs during the period of resorption of the deciduous teeth are not mentioned nor are rarer conditions such as Ewing's tumour, cherubism, and the retinal anlage tumour of infants. Osteomyelitis of infants in the mandible or maxilla goes completely unmentioned and it is incredible that the completely erroneous statement that the cessation of mandibular growth following ankylosis due to infection or injury is caused by lack of functional stimulus should be made in this book.

The association of mandibular agenesis with first arch dysplasias is not pointed out and the inclusion of radiographs to show the difference in form in agenesis from this cause and in reduced or absent growth due to infective or traumatic injury to the condylar growth centre would be desirable. It seems a pity that while the histological picture of tuberculous lesions is well portrayed, that of syphilis is omitted.

The format, the paper and the standard of reproduction in colour is first class, in fact has to be seen to be believed, and it is obvious that in terms of value for money this book is a real bargain. The fact that with one exception criticism is of errors of omission demonstrates the high quality of the remainder of the book and there is no doubt that this volume makes a most valuable addition to the library of any practising oral surgeon or stomatologist to say nothing of the help it will give the postgraduate student. The U.S. Naval Dental School is to be sincerely congratulated upon its production.

Interesting Cases and Pathological Considerations and a Numismatic Suggestion. By F. Parkes Weber, M.A., M.D., F.R.C.P., F.S.A. (Pp. iv + 77; illustrated. 18s. 6d.) London: H. K. Lewis & Co. Ltd. 1956.

Books written by medical men well past the age of 90 are few and far between, and for that reason alone Dr. Parkes Weber's booklet will arouse considerable interest. But there are other reasons. Anything from the pen of this erudite and cultured physician, who describes himself as "a diligent student of pathological phenomena on the ways and byways of a long life of medical work", is worth reading. Of the twenty essays here assembled three are original ("Nævi and Nævoid Conditions", "Steiner Voerner Syndrome", and "A Numismatic Suggestion"). The others are reprinted in amplified form from such journals as *The Practitioner*, *British Medical Journal*, *Lancet*, *Medical Press*, and *British Journal of Children's Diseases*. In the first article "My Most Interesting Case", printed in the full form in which it was submitted to *The Practitioner*, the author reminds us that he described thrombo-angiitis obliterans just before Leo Buerger's first publication. The papers vary in length from half a page to fourteen pages. The majority are dated 1954 and 1955. The earliest "A Portrait Medal of Paracelsus" first appeared in 1897. Some of the titles in their length and completeness are typical of the writer, as are the copious footnotes, references, and parentheses. There is a good index.

New Pathways in Cellular Pathology. By Gordon Roy Cameron, M.B., D.Sc.Melb., F.R.C.P., F.R.S. (Pp. vii + 90; illustrated; 16s. 0d.) London: Edward Arnold. 1956.

The introduction of various biophysical techniques into cytology in recent years has made it possible to penetrate far into the obscurities of many intracellular phenomena. Hitherto, these methods, among them the centrifugal separation and electronmicroscopic examination of distinctive organelles, such as the nucleus, mitochondria and microsomes, have been

employed mainly in seeking a better understanding of the localization of particular structures and functions in normal cells. In this small monograph, the amplification of two recent lectures, Professor Cameron has pointed out the great and productive field of research that awaits the pathologist when he turns his attention to the study of injured cells by similar methods. Naturally, in a rapidly expanding science in which many of the findings obtained by these new methods have not yet been fully fused with those of conventional microscopy, much must for the present be speculative. But enough has already been added to established knowledge for it to be no longer possible for the pathologist to remain aloof. Professor Cameron has performed a valuable service in bringing a broad survey of this modern cytology to the notice of a group of medical scientists, many of whom are conservative by nature and training. None the less, it may well provide an incentive to some of the younger and more enterprising to examine more fully for themselves the great possibilities inherent in the newer cytology.

Progress in Nuclear Energy. Series VII Medical Sciences. Vol. 1. Editors J. C. Bugher, J. Coursaget, and J. F. Loutit. (Pp. xii + 165. 42s.) London: Pergamon Press Ltd. 1956.

There are seven different contributions to this Series of Progress in Nuclear Energy. Two deal with the growing use of radioisotopes in medical diagnosis, two with advances in technique in radiotherapy by internal or external means with the aid of nuclear radiations, two with the present-day principles and standards of radiation safety and one is devoted to dosimetry of ionizing radiation. The source of these articles is mainly attributable to the International Conference on the Peaceful Uses of Atomic Energy at Geneva, August 1955. Although two of the articles here are devoted to the diagnostic value of radioisotopes, one is by two physicists and the other by a medical man. There is in no sense an overlap, however, and a very wide range of use is exhaustively treated; in fact, the first of them concludes with a bibliography extending over seven pages.

The two articles on therapy are by a master hand and in his Introduction he expresses the view that the therapeutic use of radioactive isotopes administered internally is of more fundamental interest than their use as external sources. Then follow contributions by other authors about this particular technique, upon hæmatologic therapy and the treatment of neoplasia generally either by radioactive suspensions or by colloid chromic radiophosphate, and an "accurate method" for the treatment of hyperthyroidism with I^{131}. The writer concludes that this substance is his choice in the treatment of Graves' disease in patients over 40 years of age and for younger patients with post-therapeutic recurrences.

Within this group of papers upon treatment is one dealing with various problems in the whole range of effort involving the internal use of radioisotopes. One of the biggest problems lies in the estimation of the doses received by various tissues; at present "it is rarely possible to make more than a crudely approximate evaluation of the mean tissue dose, at the best $\pm 20\%$ and often with much greater error". An important unsolved problem is whether there is any real risk of late carcinogenesis or of leukæmogenesis; time alone can give the answer, but to date the absence of any proved cases is reassuring. There are other dangers, however; the intravenous administration of 6 millicuries of P^{32} delivers a dose in the region of 100 rep to the testis or ovary.

In spite of these possibilities, the reader gets the general impression that the hazards can be met with equanimity, largely because of the general awareness of the dangers that are there when radioisotopes enter the body.

This volume of 165 pages is a mine of information which will be of the greatest service to those already, and to those about to become, engaged in a rapidly developing branch of medicine.

Noradrenaline—Chemistry, Physiology, Pharmacology and Clinical Aspects. By U. S. von Euler, M.D., F.A.C.P.(Hon.) (Pp. xxi + 382; illustrated. 87s. 6d.) Oxford: Blackwell Scientific Publications. (Springfield, Ill.: Charles C. Thomas.) 1956.

The appearance of a monograph on noradrenaline is to be welcomed especially from the hand of one of the most vigorous workers in this field. The book covers in considerable detail the vicissitudes of noradrenaline since its synthesis in 1904 by Stolz to its present position as one of the transmitter substances involved in nervous activity. Once identified as being present in the organism in 1946–8 by von Euler and his co-workers, noradrenaline has become the subject of a very voluminous and scattered literature. Sir Henry Dale in a characteristic introduction surveys the history of noradrenaline. He had studied its general pharmacological action along with Barger in 1910–11, and had noted that this primary amino homologue of adrenaline reproduced the inhibitor components of the

action of adrenaline relatively weakly, making it more accurately sympathomimetic in its detailed action than adrenaline. Somewhat ruefully with all the newer evidence now available he remarks that this fact made it more difficult for him to accept T. R. Elliott's hypothesis of adrenaline having a chemical transmitter function in sympathetic nervous stimulation. Later evidence has, however, clarified the situation—the transmitter being composed of mainly noradrenaline and adrenaline, noradrenaline being the more predominant constituent at many nerve ends. This evidence relieves us of the necessity of preserving Cannon's sympathin with its E. and I. modifications. It is suggested that the sympathin nomenclature should now be dropped as being misleading and unnecessary—the terms have served their purpose.

After a brief historical introduction the chemistry and metabolism of noradrenaline, methods of purification and biological assay are discussed in great detail, and its occurrence in the suprarenal medulla, chromaffin cells, and in nervous organs and body fluids is carefully studied. The physiology and pharmacology are dealt with in great but necessary detail followed by a description of the part it plays in adrenergic nerve stimulation and also in suprarenal and other chromaffin gland secretion and its excretion in the urine. The more recent discovery of noradrenaline in chromaffin cell tumours and sympathoblastomata and its significance are also discussed. The final chapter is devoted to a survey of the therapeutic uses of noradrenaline. This brief survey of its main contents shows that the book has a wide appeal not only to pharmacologists but to biochemists, pathologists and clinicians; in fact to all with an interest in this rapidly growing field of investigation—growing so rapidly that most of the chapters have a short series of addenda of the even more recent papers. The format and presentation are those customary for this series. The book is profusely supplied with tables and figures. While the price of the book may prevent some individual workers from having their own copy, it will be essential for all laboratories where such problems are studied.

Clues in the Diagnosis and Treatment of Heart Disease. By Paul D. White, M.D. 2nd edit. (Pp. xv + 190; illustrated. 40s.) Oxford: Blackwell Scientific Publications. (Springfield, Ill.: Thomas.) 1956.

The first volume of this small book was written at the request of medical graduates who had found a lecture on the subject by the author to be pregnant with interest and instruction. The demand for a second edition within so short a time has endorsed its usefulness. Elaborate and specialized laboratory procedures in the diagnosis of heart disease take second place here to the important knowledge that is so readily accessible to the clinician when he elicits the story of an illness from a patient and uses intelligently the natural senses during examination conducted in the patient's home or in the hospital ward. This book is intended for general practitioners, but cardiologists cannot be unmindful of the succinct statements that appear on almost every page, and the quotation—"a doctor who cannot take a good history and a patient who cannot give one, are in danger of giving and receiving bad treatment", might be mentioned as a sample. The clues it embodies are not all of the author's discovery, and they gain in value from being representative of opinion held by clinicians all over the world. Paul White can listen to, and learn from, others, and thereby add to his own bountiful store of knowledge and wisdom which he imparts delightfully to the readers of this valuable little book.

Alcoholism. A Manual for Students and Practitioners. By Lincoln Williams, M.R.C.S., L.R.C.P. (Pp. x + 62; 8s. 6d.) Edinburgh and London: E. & S. Livingstone Ltd. 1956.

Medical students receive little instruction in alcoholism from their teachers or from their textbooks, with the result that when they begin general practice, the question of alcoholism is a real problem to them. Dr. Lincoln Williams describes his little book as "a manual for students and practitioners". Convenient in size, simply and sympathetically written, and commendably inexpensive, it is needed by, and it will appeal to, both types of reader. The author rightly looks upon alcoholism not as moral depravity, but as a disease and, therefore, as a medical problem, and throughout he stresses the fact that it is also an individual problem. In fourteen short chapters, some of which are only a page or two in length, he discusses drinking patterns; personality factors; the course of alcoholism; heredity; the mental and physical effects of alcoholism; how to approach an alcoholic; medico-legal aspects of alcoholism; methods of detoxication; disruption of the drinking pattern (by conditioned-reflex treatment, apomorphine, and Antabuse); group therapy; and Alcoholics Anonymous. The book concludes with a useful bibliography and an index.

Section of Pathology

[*October* 16, 1956]

Injury as An Ætiological Factor in Tuberculosis

PRESIDENT'S ADDRESS

By Professor JOHN W. S. BLACKLOCK, M.D.

FROM time to time clinicians have drawn attention to the liability of tuberculosis developing after an injury at such sites as the bones, joints, epididymis, chest wall (pleurisy) and head (meningitis) and have stressed the fact that the trauma was usually of a trivial nature (Keen, 1906; Watson-Cheyne, 1911; Hamburger, 1912; Borthwick, 1945). Krause (1899), who repeated the classical yet controversial experiments of Schüller (1880), showed in rabbits and in guinea-pigs infected with tuberculosis that the disease rarely if ever occurred at the site of fracture but was frequent in joints which had been wrenched. More recently Debré *et al.* (1951*a*) have again drawn attention in a case, which was well investigated, to the effect of trauma localizing a tuberculous infection at the seat of injury.

The same is true of syphilis, gummata occurring at the site of trivial injury, for example on the forehead due to touching the ground many times daily during devotional practices (Lacapère and Laurent, 1918), or in scars (Chesney *et al.*, 1928), or in tattooed ar as (Aoki, 1912; Keidel and Zimmermann, 1918) though in such cases the areas tattooed with pigments containing mercury (e.g. cinnabar) remained free from lesions. As in tuberculosis, these observations have been confirmed by experimental work on the part of some of the above authors. Secondary lesions have been reported at the site of injury in many other infections—typhoid, the pyogenic group, and also those due to the viruses, as was reported as long ago as 1804 by Jenner in the case of vaccinia.

The explanation usually given is that the injury produces a "locus minoris resistentiæ"—a venerable expression, hoary with age, which means but little.

My interest in this problem, as far as it concerns tuberculosis, was stimulated by the publication of a case by Ebril and Elek (1946) in which tuberculosis occurred at the site of a penicillin injection. They stated: "The source of the infection was in all probability either the penicillin or the apparatus for its administration." Others have reported similar cases (Hounslow, 1946; Coope and Hindenach, 1947; Forbes and Strange, 1949; Douglas, 1950; and Šikl and Vaněk, 1950), and opinion varies among those authors as to whether the infection was autogenous or exogenous. The case described, however, by Coope and Hindenach in which tuberculous abscesses developed in both thighs at the site of injections suggests a hæmatogenous origin. The tubercle bacillus had been typed and proved to be human in only one of the reported cases (Forbes and Strange). Debré *et al.* (1951*b*) have reviewed the literature of syringe-borne tuberculosis, to which attention was first drawn by Bigger *et al.* (1940*a*). During 1947 to 1948 I was asked to investigate three cases of tuberculous abscesses occurring at the site of penicillin injections. The salient features of these cases are as follows:

Case I.—Male, aged 20. Active pulmonary tuberculosis with positive sputum (human type of bacillus). Treated for boils with penicillin injections into the outer aspect of thighs. About four weeks after cessation of treatment an abscess developed in each thigh in the region of the injections, from which human type of tubercle bacilli were isolated in pure culture.

Case II.—Boy, aged 14. Cervical abscess with enlarged glands. Clinically this was thought to be pyogenic and penicillin injections were given. In tissue taken from the lesion pyogenic cocci as well as human type of tubercle bacilli were isolated; histologically typical tubercle follicles were present. The penicillin injections had been given into the buttock, and about six weeks after the cessation of treatment an abscess developed in that region from which human type of tubercle bacilli were isolated in pure culture.

Case III.—Female, aged 28. Treated for a pyogenic infection of a wound by penicillin injections into the outer aspect of thighs. An abscess developed in both thighs about eight weeks after the last injection; human type of tubercle bacilli were isolated from each abscess. After the thigh-abscesses were proved to be tuberculous, radiological examination showed a healing lesion in the upper lobe of the left lung, but no tubercle bacilli were ever obtained from the scanty sputum.

These cases, particularly Cases I and III, in which tuberculous abscesses were present in each thigh, suggested to me that the infection at the site of the penicillin injection was almost certainly hæmatogenous. The first two cases occurred in hospitals where the syringes were reserved exclusively for injections and were boiled for at least ten minutes before being used. The third case occurred in the domiciliary practice of a practitioner who used

only one particular syringe for injection, washing out the syringe and needle several times after use with surgical spirit, a procedure which, as pointed out by Bigger *et al.* (1940), is not sufficient to kill tubercle bacilli.

Tuberculous lesions in muscles are a rarity and the literature, chiefly Italian, has been reviewed by Cortessi and Venturi (1948), who collected 92 cases and added 2 of their own. Some of their cases, apart from those due to trauma may, however, have been of the nature of syringe-borne tuberculosis, as the tuberculous lesions at the site of injection followed auto-therapy, anti-typhoid vaccination, &c. The authors concluded, however, that all the infections were hæmatogenous, owing to the presence in a proportion of the cases of tuberculous lesions elsewhere (lungs, glands and bones).

The possibility suggested itself to me of finding if experimental tuberculosis could be localized at the site of various types of injury, in particular those due to injections of penicillin and other substances as the trauma due to this procedure was minimal. A series of experiments was accordingly carried out, only brief details of which will be given here as they are being published in full elsewhere by my colleague, Dr. J. R. B. Williams, and myself.

Conditions Necessary for Experiment

An experimental approach to this subject demanded (1) a tuberculous bacillæmia, (2) trauma of various kinds of which that of a minimal degree would give the least controversial results, owing to the avoidance, as far as possible, of injury to the blood vessels causing hæmorrhage and allowing the bacilli to escape into the damaged tissues. For the first we found that injection of approximately 500,000 human tubercle bacilli (H.37Rv) in 0·5 ml. saline into the left ventricle of rabbits was the most satisfactory procedure. To accomplish this, the thorax was opened in order that the manipulation could be undertaken visually as this ensured that the bacilli had actually entered the arterial side of the circulation. Similar experiments were performed on guinea-pigs but in these the dose of bacilli was approximately 125,000 bacilli in 0·25 ml. saline. By this means it was found that in rabbits tubercle bacilli could be isolated from 1 ml. of blood from fifteen minutes to twenty-four hours after inoculation. Of much importance, as it helps to explain the mechanism of infection of an injured site, was the finding that in rabbits tubercle bacilli could be isolated from catheter specimens of urine within two hours of inoculation, and at varying intervals up to twenty-four hours. At this early time it is not possible for any gross lesion to have developed in the kidney and the only explanation likely is that the tubercle bacilli had passed through the glomerular capillaries into the sub-capsular space and so into the urine.

For the production of trauma, various forms of injury were used, the chief being the injection into the muscles of penicillin, saline, peptone or other substances, as mentioned later, the site of such injections being marked on the overlying skin, though this was not altogether a trustworthy guide.

It was assumed that any tuberculous lesion developing in the muscles at the site of injury was due to the injection, as muscle tuberculosis in the animal experimentally infected with small doses of human strains, is, as in man, exceptionally rare. Such small doses (500,000 bacilli) as were employed in rabbits produced a very chronic disease, the animals, when allowed to live, being still apparently healthy six months later. This rarity of muscle tuberculosis in the rabbit experimentally infected with small doses of tubercle bacilli has also been commented on by Cobbett (1917); Calmette (1928) in his monumental work on tuberculosis makes no mention of muscle lesions, and neither do Corper and Lurie (1926) in their work on the localisation of tubercle bacilli in the tissues of different animals. Indeed, in our own experiments muscle tuberculosis was never found until after the sixth week of infection and then only with extreme rarity, though many blocks of muscle tissue were examined. The lesions occurring after the sixth week of infection may, of course, have been due to a secondary spread from lesions in the various viscera caused by the original inoculation. In the case of guinea-pigs, muscular lesions were never observed. The rarity of muscle lesions may be due to lactic acid, which is produced in muscles, having an anti-mycobacterial effect (Dubos, 1953).

The Effect of Trauma to Muscles

As was to be expected, the coarser forms of trauma such as the removal of a piece of muscle, severe blows, the insertion of ligatures, almost invariably resulted in a tuberculous lesion developing at the site, due possibly to the bacilli escaping from the severed vessels into the damaged tissues. The fact that experimental pyogenic infections sometimes localized around stitches was observed nearly a century ago by Billroth (1865). Silk ligatures which we used contain a relatively high proportion of silicate. Kettle (1924) showed experimentally in mice and in rabbits infected by the intravenous route with tubercle bacilli (human or bovine) that silica introduced into the muscles caused a heavier concentration of tubercle bacilli at that site than did turpentine or calcium chloride, both of which

caused a more acute inflammatory response. Indeed, Kettle's Presidential Address to this Section in 1931 dealt partly with this very subject.

The more minimal forms of injury such as intramuscular injection were studied in three groups of rabbits, all infected by the intracardiac route as already described. On the day of infection and the day following the animals in group (*a*), 10 rabbits, were injected with 0·3 ml. saline intramuscularly; in group (*b*), 10 rabbits, were injected with 0·3 ml. crystalline penicillin (300,000 units per ml.); and in group (*c*), 4 rabbits, were injected with 0·3 ml. 2% peptone. The animals were all killed before the sixth week of infection and the muscles at the sites of the injection were investigated histologically for tuberculous lesions as well as uninjected muscles at some distance from those sites to serve as controls. Tuberculous lesions were found: in group (*a*), saline—in 2 out of 10 injected on the first day of infection and in none on the second; in group (*b*), penicillin—in 6 out of 10 on the first day and in 4 out of 10 on the second; in group (*c*), peptone—in all 4, both on the first and seconds days (Figs. 1 and 2). In all these groups no tuberculous lesion was found in the

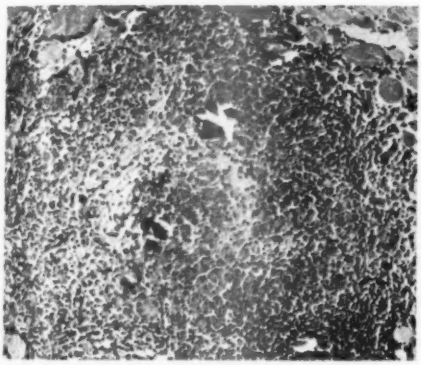

FIG. 1.—Tuberculous lesion at site of intramuscular injection of penicillin. Caseous centre and surrounding cellular reaction. × 90.

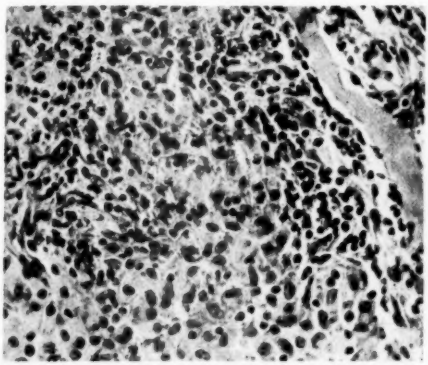

FIG. 2.—Tuberculous lesion at site of intramuscular injection of peptone. Endothelioid cells with some large mononuclears and round cells. × 230.

control muscles. It is unfortunately not desirable to apply any test for statistical significance to these results on account of (1) the difficulty of always finding the site of injection and (2) the variation of the response to tuberculous infection on the part of a mixed strain of rabbits, as commented on by Lurie (1928). It is apparent, however, that the tuberculous infection localized much more frequently at the site of injections of penicillin and of peptone, given on the first or second day of infection, than at the site of injections of saline. This finding, together with the absence of lesions in muscles not injected, is of some significance. Undoubtedly, as we shall afterwards point out, the penicillin and peptone had introduced another factor.

These experiments were repeated in guinea-pigs which had been infected by the same route as the rabbits, but with 0·25 ml. of a suspension containing approximately 125,000 bacilli of the same strain. In guinea-pigs, however, distaquaine penicillin required to be used in place of crystalline owing to these animals quickly wasting and dying in a few days after the injection of the latter. 0·2 ml. of distaquaine penicillin (300,000 units per ml.) was found to be fairly well tolerated, probably owing to the slower absorption of the penicillin.

The experiment was carried out on similar lines to that in the rabbits, injections being made into the muscles on the day of infection and on the day after in (*a*) 14 pigs—0·2 ml. saline; (*b*) 16 pigs—0·2 ml. distaquaine penicillin; (*c*) 6 pigs—0·2 ml. of the agent used for suspending the penicillin; (*d*) 4 pigs—0·2 ml. of 2% peptone. When these animals were killed twenty-eight days or less after the last injection, tuberculous lesions were found in the muscles at the injection site in group (*a*) saline—in none out of 14 injected on the first day and in 4 out of 14 on the second; in group (*b*) penicillin—in 4 of 16 on first day and 7 of 16 on second; in group (*c*) suspending agent—in 4 of 6 on first and second days; in group (*d*) peptone—in all 4 on both first and second days.

Though the results, on account of the same difficulty as experienced with rabbits, cannot be submitted to statistical proof, they are indicative that the penicillin, the suspending agent and the peptone are more liable to localize a tuberculous infection at the site of injection than saline. In all these groups, sections taken from the muscles not injected in each animal showed no tuberculous lesion.

The Effect of Trauma to Joints

It is recognized, as already mentioned, that injury to a joint in the human subject with primary tuberculosis elsewhere occasionally results in tuberculous disease of the joint. We decided to try if we could prove this experimentally. Tuberculosis of the joints of rabbits experimentally infected with human type of tubercle bacilli may occasionally occur even when the disease is pursuing a chronic course. This has been noted by Cobbett (1917) and also by Calmette (1928). In a series of 12 rabbits killed up to forty days after infection with the dose of bacilli used in these experiments, we never observed any histological evidence of tuberculosis in the larger joints like the knee or the elbow. In another 6 rabbits, 0·1 ml. of crystalline penicillin (500,000 units per ml.) was injected into the right knee and right elbow about one hour after intra-cardiac infection. In 4 the knee and in 6 the elbow showed histological tuberculous lesions in which tubercle bacilli were demonstrable when the animals were killed forty days or less after the infection (Fig. 3). The corresponding joints on the opposite side of these animals showed no lesions histologically. In another series of rabbits in which joints were struck a sharp blow, tuberculous lesions were observed in a high proportion of the injured joints, but in these it was obvious at the time of experiment that some bruising of the superficial tissues had occasionally resulted.

Primary Lung Focus Experiments

The tuberculous bacillæmia produced by intra-cardiac inoculation is highly artificial and bears little resemblance to what may happen in the human subject with, say, a tuberculous lesion in the lung, though sometimes in these cases tubercle bacilli do find their way into the blood stream to produce secondary lesions in kidneys, bones, joints, meninges and elsewhere. It was decided, therefore, to make an attempt to produce a lesion in the lung of the rabbit and of the guinea-pig, resembling the primary lung focus in the child, as described by Blacklock (1932). Insufflation of tubercle bacilli into the trachea caused multiple lesions in the lungs and, therefore, was undesirable. It was found that by injecting 0·02 ml. of a suspension containing approximately 500 bacilli into the superficial part of the lung, exposed at thoracotomy, a lesion closely resembling the primary lung focus of the child could be produced. Indeed, in the successful experiment the resemblance was striking for, as in the child, the infection also spread by the peribronchial lymphatics to the hilar glands and thereafter became generalized.

In a small series of rabbits in which these lung foci had been produced, it was noted that the spread of the disease to the other lung and the other organs did not become histologically apparent until about the fourth week and it was assumed that shortly before this time tubercle bacilli were escaping from the lung lesion into the blood stream. To test this assumption coarse silk threads were inserted into the muscles of 2 rabbits during the first, second, third and fourth weeks, after the injection of tubercle bacilli into the lung, as already described. Tuberculous lesions occurred only around those ligatures inserted during the fourth week.

In a further series of 11 rabbits infected in the same way to produce a primary lung lesion, intramuscular injections of 0·25 ml. of crystalline penicillin (300,000 units per ml.) were made during the fourth and fifth weeks of infection. Of the 11 injections made during the fourth week, 2 showed evidence of tuberculous infection at the site of the injection in the muscle, as also did 3 of the 11 injections made during the fifth week (Figs. 4 and 5). In all these animals lung foci had been produced, and in addition there was histological evidence of tuberculous involvement of the other lung and occasionally of the spleen and kidneys. Similar experiments were carried out in guinea-pigs, using distaquaine penicillin for intramuscular injection, but in only 1 out of 4 did a lesion result at the site of the intramuscular injection, though all showed, in addition to the lung focus, generalized involvement of the other organs.

Though disappointing, these results do resemble what occurs in the human subject with pulmonary tuberculosis, as in the human the occurrence of secondary tuberculous lesions at the site of injury is not common.

The possibility then suggested itself, could a tuberculous infection be localized in the lung after a primary infection of the thigh muscles? It is well recognized that in the rabbit the lung is one of the organs most affected, irrespective of the route of infection. Indeed Dr E. G. Rees and I have found that human tubercle bacilli injected into the suprarenal localize very quickly in the lung. A small series of experiments, as yet incomplete, are in progress in which human tubercle bacilli were inoculated into the muscles of the right thigh and seven to fourteen days later 0·1 ml. of indian ink (to serve as a guide) was injected superficially into one aspect of a lobe of a lung and into the corresponding site on the other aspect 0·1 ml. of crystalline penicillin (500,000 units per ml.). In some of the animals killed about two months later the infection was found to have localized at the site of these injections, producing at the penicillin site an appearance very similar to that seen where

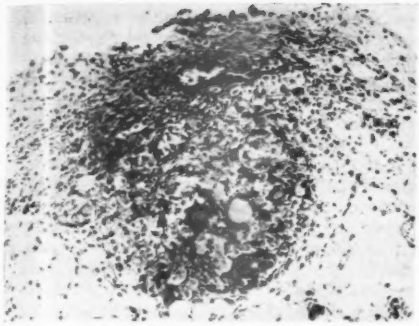

FIG. 3.—Tuberculous lesion in knee-joint injected with penicillin. Tubercle follicle with giant cell in fatty tissue below synovial membrane. × 100.

FIG. 4.—Lung focus produced by direct inoculation of tubercle bacilli into lung of rabbit. × 10.

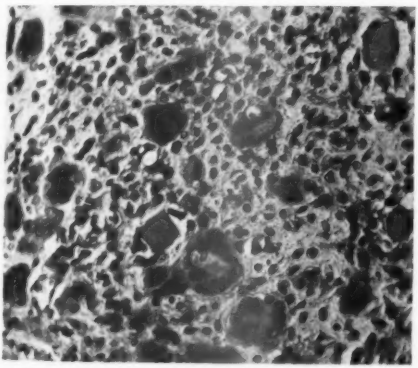

FIG. 5.—Same rabbit as Fig. 4. Tuberculous lesion in thigh muscles injected with penicillin five weeks after tubercle bacilli had been inoculated into lung. Endothelioid and giant cells: small fragment of muscle tissue. × 200.

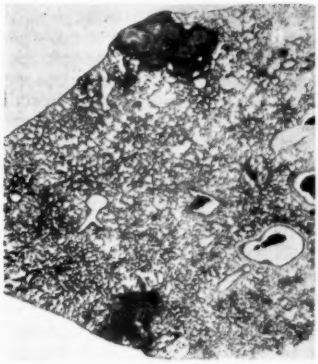

FIG. 6.—Tuberculous focus in lung of rabbit at site of penicillin injection (top): lower focus due to injection of indian ink to serve as marker for site of penicillin injection. Rabbit had been infected by inoculation of tubercle bacilli into thigh muscles seven days before injections of penicillin and ink into lung. × 5.

the bacilli had been injected directly into the lung to produce a primary lung focus (Fig. 6). Such a result may serve to explain why tuberculosis of the lung so frequently follows such diseases as measles, whooping cough and influenza, in which we know the lungs are injured by the inflammatory processes occurring in these diseases.

THE FACTORS INVOLVED IN THE LOCALIZATION OF THE INFECTION

In these experiments there was a tuberculous bacillæmia, and any gross injury, such as bruising, would allow the bacilli to escape from the ruptured capillaries, or, if short of rupture the capillaries were so damaged as to cause thrombosis, then the bacilli might become arrested at the site of the thrombosis and there multiply, a tubercle follicle eventually forming around them. This is the likely explanation of some of the experiments in which a tuberculous lesion resulted at the site of a blow or in the area where silk or wire sutures had been introduced. But it is hardly sufficient to explain the positive results at the sites of injection of penicillin or peptone as in these hæmorrhage was a rarity and the small needle used (size 18) would not be likely to cause sufficient trauma to produce thrombosis.

The other factor was the effect of the penicillin or the peptone on the tissues into which these substances had been introduced. With the early penicillin preparations, most of which were not absolutely pure, local reactions at the site of injection, such as necrosis,

œdema, and cellular infiltration, sometimes occurred (Robinson, 1943; Selbie and McIntosh, 1943; Hamre *et al.*, 1943; Darmady, 1946). But this has not been reported with the purer crystalline forms. To ascertain if any damage resulted, 0·2 ml. crystalline penicillin G (20,000 units) was injected into the muscles of a series of guinea-pigs, marking the site of injection in the overlying skin. In a few of these animals killed on the fourth day a small microscopic necrotic focus with surrounding macrophage reaction was found. These foci were also observed in some of the animals as late as the seventh day after injection, but not afterwards. It was not easy to find such lesions and the muscle at the site of injection required to be serially sectioned. Of interest to us, however, was the macrophage response in these areas. Peptone injections produced a greater reaction on the part of these cells than did penicillin. The macrophages were probably attracted to the site by the foreign substances injected and in those experiments where the animals had been previously infected with tuberculosis, some of these cells, having already phagocytosed tubercle bacilli in the perivascular regions of the capillaries, might have carried them to the site of injection. It is well known that the large mononuclear leucocyte actively phagocytoses tubercle bacilli (Sabin and Doan, 1927; Lucké *et al.*, 1933; Lurie, 1932, 1934; Vorwald, 1932; Jensen *et al.*, 1935), and in the cytoplasm of these cells the bacilli may multiply and survive for at least a time (White, 1927; Lurie, 1942; Suter, 1952), though as the bacilli multiply, particularly the H.37Rv strain as used in these experiments, the mononuclears die. The death of these infected cells has been reported to be more rapid in the presence of penicillin by Mackaness (1952), though penicillin has been extensively employed as a bacteriostatic agent in tissue culture (Gey *et al.*, 1945).

To help to explain what was occurring a small series of guinea-pigs were injected *intraperitoneally* with (*a*) 2 ml. crystalline penicillin (60,000 units), or (*b*) 2 ml. peptone (2%), or (*c*) 2 ml. saline; the animals were killed one to two days later. In films made from the scanty fluid in the peritoneal cavity, the cellular response in groups (*a*) and (*b*) killed one day after intraperitoneal injection consisted of polymorphs, lymphocytes and mononuclears, while in those killed two days afterwards the cells were mainly mononuclears. In group (*c*) very scanty cells were found. On histological examination of the omentum from these animals, an increase in mononuclear cells was observed, particularly around the capillaries and it seemed possible that it was these cells that were conveying the bacilli from the region of the capillaries into the peritoneal cavity. To verify this assumption, 26 guinea-pigs were infected by the injection of tubercle bacilli (H.37Rv) introduced into the left ventricle, as previously described. On the day of infection or the day after, the peritoneum was injected with (*a*) 2 ml. peptone solution—4 pigs; (*b*) 0·5 ml. crystalline penicillin (60,000 units)—14 pigs; (*c*) 2 ml. saline—8 pigs. In films made from the peritoneal exudate of group (*a*) scanty tubercle bacilli were found in all 4 animals, and in group (*b*) in 10 of the 14, whereas in group (*c*) no bacilli were found in any of the animals. The bacilli were chiefly found inside large mononuclear cells (Fig. 7) and cultures of the

FIG. 7.—Macrophage (from peritoneal fluid of guinea-pig) containing several tubercle bacilli; peritoneum injected with penicillin on day of intracardiac infection with tubercle bacilli. × 650.

scanty peritoneal exudate in such cases yielded a few colonies of tubercle bacilli on Löwenstein's media, whereas in all the other cases no growth was obtained. It thus seemed a reasonable conclusion that the large mononuclear leucocyte was the vehicle by which the bacilli were conveyed from the region of the vascular system to the site of injury. It is known that the capillary vessels of the mesentery and omentum are more permeable to suspended particles than the capillaries elsewhere (Cappell, 1930). Kusnetzowsky (1929) has also shown that in inflamed areas particles of indian ink pass through the endothelial cells and are phagocytosed in the extra-vascular spaces by polyblasts; Menkin and Menkin

(1931) have also demonstrated the same for graphite particles. The cellular reaction around sites of minor trauma, including those due to intramuscular injections, is mainly on the part of the mononuclear cells, whereas with more severe injury involving the death of more tissue, more polymorphonuclear leucocytes are attracted in the first place.

Another factor which should be considered is the possible liberation of histamine from the focus of injury and the part played by it. Findlay (1928) was able to localize hæmatogenous pyogenic infections as well as vaccinia at the sites of intramuscular injections of histamine. It would be interesting to repeat his experiments in a tuberculous infection. Histamine undoubtedly will be liberated in areas of more severe injury and will cause some increased permeability of the capillaries of the part, but it is doubtful if sufficient is liberated as the result of a simple intramuscular injection, which admittedly may cause temporary interstitial pressure changes, which might have some transient effect on capillary permeability. Sager and Nickel (1929) have also demonstrated how *Streptococcus viridans* introduced intravenously will localize at the site of sterile abscesses produced by 10% silver nitrate solution, and Kettle (1924) showed how tubercle bacilli inoculated intravenously localize at the site of silica injections.

The very controversial question now arises, where do these mononuclear leucocytes arise? Advisedly we have used this term for these cells as it makes no definite implication as to their origin. Sabin *et al.* (1925), Sabin and Doan (1927) and Cunningham *et al.* (1925) maintain that the mononuclear cells are derived from the clasmatocytes and are of reticuloendothelial origin, and that they actively phagocytose tubercle bacilli, whereas the monocyte, which appears later, is not so phagocytic and eventually differentiates into the epithelioid cell. They observed that the monocytes in the peripheral blood in acute experimental tuberculosis may harbour but probably do not destroy tubercle bacilli. Cappell (1930) from his extensive experiments on vital staining concluded that only a small proportion of the mononuclear cells of the tissues is derived from the monocytes of the blood or from the tissue histiocytes, and that their main origin is from the cells of the adventitial sheaths. Ebert and Florey (1939) found that at least some of the mononuclear leucocytes originate from the blood monocyte and that the tissue histiocyte does not migrate into an injured area but that mononuclear phagocytes may develop in the tissues. From our own observations in experimental tuberculosis we have been impressed that in the very early stages of an infection large numbers of mononuclear leucocytes (macrophages) are found around some of the smaller blood vessels in the infected region, and most likely the majority of these cells originate in that situation from some stem cell. Lurie (1934) has made similar observations and has further noted that these collections of mononuclear cells push the endothelial lining of the vessel ahead of them and so encroach on the lumen, thus being in a most advantageous position for phagocytosis of any bacilli in the blood stream which may become slowed at this point, due to the narrowing of the capillary.

Lastly the effect of the penicillin and the peptone on the localization of the infection must receive some consideration. It was observed during the progress of this work that where saline was injected bacilli rarely, if ever, localized; in the few cases where this happened a small vessel may have been pierced by the needle, allowing blood and bacilli to escape. Ungar and Muggleton (1946) have reported that the addition of penicillin to culture media resulted in an increased growth of the tubercle bacillus, while Iland and Baines (1949) from their experiments concluded that on account of the penicillinase produced by this organism it had no such effect, though their experiments were not identical with those of the former workers. Rivière *et al.* (1947) found that guinea-pigs infected with tubercle bacilli and treated with penicillin die much more rapidly than the controls not so treated. On account of the extreme toxicity of penicillin for these animals it seems more likely that death was accelerated by the penicillin alone. To find if penicillin had any effect on the progress of tuberculous infection in rabbits we infected 4 rabbits by intravenous inoculation with 0·01 mg. tubercle bacilli (H.37Rv) and another 4 with the same dose into the left ventricle. To 2 of the intravenous group and 2 of the left ventricle group, 1 ml. of crystalline penicillin (100,000 units) was injected intravenously every day for four weeks. The other 4 were given no injections and served as controls. All 8 animals were killed four weeks after the penicillin group had received their last injection, when no difference was found in the severity or the distribution of the lesions in those which had received penicillin and those which had not. Thus we can conclude that at least in the rabbit penicillin does not stimulate the growth of tubercle bacilli as judged by the lesions produced.

When all the results of these experiments are considered the conclusion, though still controversial, may be reached that the macrophage is responsible for carrying the infection. Thus a cell which does so much for the surgeon, scavenging dead tissue and phagocytosing ligatures, and for the physician by removing the products of deep-seated inflammation in the lung and elsewhere has been found wanting. For having phagocytosed the tubercle bacilli in the blood stream, but more probably in the immediate vicinity of the capillaries, it

still goes on carrying out its normal function by being attracted to a foreign substance introduced into the tissues or by damaged tissue and thus spreads the disease.

It is my privilege to thank my two colleagues, Dr. J. R. B. Williams and Dr. E. G. Rees, who have helped me in some aspects of this work, and for their permission to use some of our joint work, as yet unpublished, for this Address. I would also wish to express my gratitude to two technical assistants, Miss June D. Hart and Mr. Geoffrey Brown, who at different times have given me invaluable assistance, and also for secretarial assistance to Miss M. Ash.

The cost of the earlier part of this work was defrayed by a grant from the Medical Research Council.

Joint Contractures in Children

By DENIS BROWNE, F.R.C.S.

JOINT contractures in children may be classified into the congenital and acquired, and these classes divided again according to whether the contracture is intrinsic or extrinsic. In the intrinsic class the limitation of movement is due to structures of the joint itself, particularly the fibrous tissues round it; in the extrinsic contractures the limiting structures are outside the joint, most usually being muscles, though occasionally webbing of the skin is responsible.

CONGENITAL CONTRACTURES

Intrinsic

(1) *Normal contractures:* It is not often pointed out that normal newborn babies have the limitations of the adult range of joint movement which might be expected from their previous cramped position. The hips, the knees, and the elbows will not fully extend; and the feet will not go into full equinus. The normal instinctive muscular movements of this age soon dispose of these slight limitations.

(2) *Contractures due to abnormal pressure:* In my opinion long-continued pressure on a limb has the same effects if it occurs before birth as it is generally recognized to have if it occurs afterwards. These effects seem to be due to an interference with the normal blood circulation, particularly the venous return, which of course would become obstructed at a much lower pressure than the arterial. This increased pressure may be either mechanical, due to the uterine structures not expanding at the correct rate to keep pace with the expansion of the growing fœtus; or hydraulic, due to increased tension of the amniotic fluid. Though increased tension of this fluid is usually associated with increase in its amount (that is to say hydramnios) increased tension may be present without increased amount, and increased amount without increased tension. The classical example of this process is the degeneration of the retina when its venous return is obstructed by increased pressure of the intracranial fluid. Though this process is universally recognized, it is curious to note the opposition to the hypothesis that a similar obstruction by increased hydraulic pressure may occur *in utero*.

There are two results of this obstruction:

(*a*) The muscles naturally fail to develop properly.

(*b*) There is a thickening and stiffening of the fibrous tissues around the joints, which is not easy to explain.

The study of contractures of this kind involves the investigation of the mechanical conditions of the pregnancy that produced them. This line of research is neglected in the present very fragmented state of medicine, as it involves the territory of two definitely divided and firmly "closed shops", those of orthopædics and obstetrics. It will be found by anyone undertaking it that the results confirm the working hypothesis upon which it is based.

Hydraulic compression would, of course, affect all four limbs equally, the effects being more severe the further the tissues involved lie from the pump of the heart. A significant proportion of these children will be found to have pregnancy histories of hydramnios; and often they emerge from the uterus stiffened in a form that could only be possible in a cavity of abnormal size; e.g. with extended hips.

Those, on the other hand, who have developed in a cavity too small for them will have the compression effects confined to those parts which are unsheltered; most often, of course, the legs and feet. Usually the arms escape, being sheltered by the huge fœtal head; but rarely they may be caught in the "wooden soldier" position, straight down alongside the body. The mothers give pregnancy histories of the kind that may be expected, these being particu-

larly valuable if they have experience of a normal pregnancy for comparison. They are small in the later months, often remarking that "all the neighbours were surprised when I had a baby"; and, in addition, nearly always are very uncomfortable.

Treatment: Treatment of contractures of this type consists mainly in cherishing and preserving the deficient muscles. The mistake is not infrequently made of attacking such structural deformities as flexed wrists and knees without considering that the real trouble is not the structural deformity, but the lack of function. These joints respond very badly to manipulations followed by immobilization in plaster of Paris; though it is possible to improve the position in this way the deformity steadily recurs, while the immobilization has inevitably weakened the muscles.

Extrinsic

Leaving out such rare and intractable conditions as webbing of the limbs at the elbows and knees, the important contractures in children are those which are due to malposition *in utero*, that is to say that the child has been lying in an abnormal position. Two of the three stock varieties of moulding deformities of the feet, club-foot and metatarsal varus, belong to this category; the third, metatarsal valgus, is due to mechanical compression in the normal position. A most important member of the first class is what I call congenital postural scoliosis, due to the child lying with the spine bent sideways *in utero*. The amount of the contractures in this condition can be best demonstrated by X-rays taken in three positions. The first is with the child lying as he does when contentedly at rest. The second shows him with the spine bent as far as it will go in the direction of the curve, and the third shows the curve corrected as far as possible. It is urgently necessary to diagnose and correct this deformity before the child begins to sit up and walk; or else the combination of body weight and unbalanced muscular action will cause a rapid and accelerating increase of the curve into the most intractable and crippling condition of "idiopathic scoliosis". In my opinion idiopathic scoliosis is a missed congenital scoliosis.

Acquired Contractures

The most important of these contractures are due to unbalanced muscular action, caused either by cerebral palsy or by poliomyelitis. The commonest crippling effect is the setting down of the foot into equinus. In cerebral palsy this is due to the excess of power in the muscles of the calf over those which dorsiflex the foot; in poliomyelitis to the very common paralysis of the peronei and extensors of the ankle. In both cases these factors are reinforced by the action of the bedclothes in pushing the feet downwards and inwards. One of the most important of the many gaps in classical splints is the lack of one to counter this equinus, the commonest of all elements in deformities of the feet. I have designed an "equinus splint" which can be worn at night; if it is not altered too far from its original design it will be found effective. Applied early enough it will avoid the only too common fixed deformity, which should never be allowed to occur. It is worth mentioning that many centres for the treatment of cerebral palsy do not draw a sufficient distinction between a spastic and a fixed equinus; one can see attempts to get a child to "relax" an ankle which is firmly fixed by acquired contractures round the joint. My treatment for ankles in this state is to work them up gradually into calcaneus by a series of walking plasters applied without an anæsthetic, and when a satisfactory range of movement upwards has been attained, to keep it by means of the equinus night splint. I thoroughly dislike the common tenotomy of the tendo achillis; it is so easy to do too much or too little.

Joint Contractures

By Trevor H. Howell, F.R.C.P.Ed.

When the former municipal infirmaries for the chronic sick were taken over under the National Health Service, several surveys were carried out by teams of observers. Perhaps the best known of these were by Professor A. P. Thomson in Birmingham and by McEwen and Laverty in Bradford, all of whom were surprised to find joint contractures in a large number of bedridden patients. Professor Thomson remarked in his Lumleian Lecture of 1949: "We speculated much about the cause of this condition which I had never encountered before. . . . The contractures to which I would draw attention are usually found in very old people who have been long in bed. The posture is one of extreme flexion; the knees are drawn up to the abdomen, the heels touch the buttocks, the arms are held close to the mouth and the chin rests on the chest. The wrists and fingers are sometimes freely movable; when feeding, either hand is used to stuff food into the mouth without the help of a spoon or fork. Such patients are difficult to examine. Left to themselves they pull the bedclothes over their

faces and lie motionless for hours. In all that we have examined, we have found the plantar responses flexor, but it was hardly possible to be certain of the tendon reflexes. Rough testing of sensation showed no gross change, but vibration sense was absent."

McEwan and Laverty (1949) found joint contractures in 524 out of 700 patients whom they examined. They noted that these changes occurred with great frequency in conditions limiting or preventing movement in the limbs such as arthritis or cerebral thrombosis.

Types of Contracture

Those of us who work in hospitals for the chronic sick are often asked to see patients with joint contractures or flexion deformities with a view to advising on their treatment. Since such cases have usually been neglected for some years previously, this is often a very difficult problem. During the last ten years I have made a study of contractures at St. John's Hospital, Battersea, and at Queen's Hospital, Croydon, which between them serve nearly half a million people. Observation of a number of such joints has allowed their separation into three different groups:

(1) Postural contractures.
(2) Contractures due to chronic arthritis.
(3) Contractures due to disease of the central nervous system.

Each of these groups is an entity on its own and shows a different response to treatment. This was recently confirmed by the American trials of the drug zoxazolamine and by my own experiments with other relaxants and with ultrasonic radiation.

Postural contractures are the consequence of maintaining a flexed position in bed, under-treatment, and a desire by the patient to withdraw from the world. The skeleton of such cases usually shows considerable decalcification but the articular changes are not, as a rule, marked. Old people of this kind resist any attempt to move their joints; but in the early stages vigorous treatment can overcome the tendency of flexion deformity if the patient will co-operate.

One woman of over 80 years of age, living in a workhouse, took to her bed and there proceeded to curl up. She objected to being moved or washed and refused to straighten her legs. Within two years there was such shortening of her hamstrings and wasting of her quadriceps that she possessed a fixed flexion deformity. The left arm was also held close to the mouth and the chin rested on her chest.

Another type of postural contracture may occur in association with chronic ulcers of the feet or legs. If patients with such lesions are allowed to stay in bed for long periods, they assume a flexed position of the lower limbs. After a time, the hips and knees become relatively fixed in flexion while the patella may even become adherent to the femur. Eventually a definite contracture occurs which prevents the patient from standing or walking.

Joint contractures in arthritis.—In the course of rheumatoid arthritis the patient tends to get into a vicious circle of joint pain, muscle spasm, and immobility in a position of flexion. This eventually gives rise to a condition in which the flexor muscles become hardened and thickened through continuous spasm. The corresponding extensor muscles are thin and wasted. Around the joints themselves, the inflammatory products favour fibrous deposition, so that the peri-articular and articular layers of tissues get inextricably mingled together. It is possible for the ends of two bones to become fused so that it is not possible to see where they have joined. Such bones also have a very thin bony cortex and are particularly liable to snap if moved forcibly.

However, flexion deformities do not constitute all the contractures occurring in chronic arthritis. There is often an element of adductor spasm as well as flexor hypertonus: and the distal part of the extremities may develop all kinds of bizarre muscle pulls. This was first mentioned by Charcot (1881).

Different joints have different tendencies when they become the seat of contractures. The cervical spine usually bends laterally and this deformity may be so marked as to cause bedsores of the pinna. The shoulder-joint often develops an upward subluxation of the humerus which prevents adequate abduction of the arm. This syndrome was described by Howell (1950). The bones, ligaments and soft tissues become fused, so that any abduction of the arm is performed by movement of the clavicle and scapula.

Elbows: When the elbow-joint is the seat of contracture, it becomes flexed and cannot be fully extended. Sometimes there appear to be considerable bony deformities, chiefly affecting the lower end of the humerus and the upper part of the ulna and radius. In a long-standing case bony ankylosis takes place. There may be some upward or backward displacement of the ulna, which can actually perforate the lower end of the humerus to cause an immobile fixed joint deformity.

Carpus: The changes in the carpus due to rheumatoid arthritis, are, of course, well known

and will not be described further. The point of interest is to note that marked structural anatomical change may not greatly impair function.

Fingers: It is difficult to formulate an adequate classification for the deformities of the fingers due to rheumatoid disease. The general tendency to ulnar deviation and the frequency of generalized flexion has been frequently described. But there is also a group of patients with hyperextension of certain joints, usually the proximal interphalangeal articulations. At times flexion of the more distal joints may be combined with extension of the proximal joints but the distribution of the contractures is capricious.

Hips: In the lower limbs, the hips are rarely affected by rheumatoid arthritis, but many patients showing rheumatoid changes in other joints have osteoarthritis of the hips. Some of these develop an "excavated acetabulum". If these patients are allowed to become immobile, the spasm of their flexor and adductor muscles produces a contracture of the hip with secondary flexion and adduction of the knees. The deformity tends to become progressive and, as a result, the inner aspects of the knees approximate and press upon each other. This leads to necrosis and ulceration. At other times, the heel of one contracted leg may press upon the other with such force as to break the bones. In consequence, compound fractures may result and these are particularly difficult to treat.

Knees: The main deformity of the knee is caused by shortening of the hamstrings. This first produces flexion of the joint, which becomes immobilized by fibrosis. Later, the head of the tibia may be drawn backwards behind the lower end of the femur as soft tissues, capsule and ligaments are destroyed. Such a subluxation causes undue pressure in the popliteal space upon nerves and vessels. In consequence there ensues marked œdema of the foot together with trophic disturbances. This train of events, it will be seen, is all the result of spasm of the flexor muscles and corresponding wasting of the extensors. Another factor, which often hinders effective treatment, is the liability of the patella to become adherent to the articular anterior surface of the lower end of the femur. This, by mechanical means, prevents full extension of the joint and thereby favours a flexed position.

Ankles: The deformities of the ankle in rheumatoid arthritis may be due to poor muscle tone and the bed-fast state when dropped foot and external rotation are found. At other times the foot is fixed at a right angle to the lower leg. Alternatively, a combination of the two may be found with foot drop and fixation both existing.

Neurogenic contractures.—The most frequent cause of neurogenic contractures is cerebral thrombosis, followed by hemiplegia. This gives rise to flexion deformities on the affected side, chiefly involving the knee, wrist and elbow. Similar deformities may occur in the course of untreated subacute combined degeneration of the cord, disseminated sclerosis, or be a rapid complication of certain forms of encephalitis.

When the contracture is due to disease of the central nervous system, the dysfunction is usually a simple hypertonus of the flexor muscles. Sometimes, however, there is also an element of adduction, particularly at the shoulder- and hip-joints. At the ankle-joint, weakness of the anterior tibial muscles may give rise to a form of foot-drop, with some inversion, in bed-fast patients. With some long-standing examples of hemiplegia, the tendons causing dorsiflexion of the toes tend to become taut. This may cause the phalanges to ride up on top of the metatarsal heads. One consequence of this is to make the plantar responses hard to elicit.

It should be noted that contractures of neurogenic origin are often associated with trophic changes, such as œdema of the feet. For this reason, it is dangerous to employ splinting in an attempt to correct deformities of this origin. The continued, and often increasing, muscle hypertonus sometimes forces the edge of a splint into the devitalized tissues. This can give rise to ulceration, necrosis and even gangrene.

Treatment

The treatment of a joint contracture, and the likelihood of success, depend chiefly upon its origin. Postural changes seem to depend upon the mental attitude of the patient. If an old woman is determined to curl up and hide away from the world, like an animal, no physical treatment is likely to help her.

Neurogenic contractures have their origin in damage to the central nervous system. Until recently, it has not seemed possible to affect them by drugs. But reports on the use of zoxazolamine (Flexin) combined with chlorpromazine suggest that progress may now be possible on these lines. Surgical methods, such as tenotomy or capsulotomy, have a limited place in patients with ability to co-operate. The danger is to cut too far or too deep, leaving a flail limb after the operation.

Arthritic contractures, in my experience, pass through three separate stages before becoming established. The first stage is that of simple reflex muscle spasm, arising from an inflamed and painful joint. This usually produces an attitude of flexion, with some

wasting of the extensor and abductor muscles as first described by Charcot (1881). The second stage shows the deposition of inflammatory products within and around the joints which tend to become organized and produce fibrosis. The third stage is one in which the bony changes predominate. Ankylosis, subluxation and osseous deformity now produce a mechanical obstruction to movement.

The first phase of the contracture is compounded of inflammation, pain, and muscle spasm. The sequence of events may be interrupted at any of these three points, either by general measures or by local treatment. For example, intra-articular injection of hydrocortisone will often diminish the inflammation and thereby stop the formation of a contracture. Injection of procaine will lessen the pain, thus relaxing the muscle. Injection of 0·5 mg. of Prostigmin can relax the muscles which are in spasm, thereby lessening the pain and disability. Similar results may also be obtained by various forms of physiotherapy.

In the second stage of contractures we have as our chief difficulty the presence of fibrosis and adhesions. It is usually necessary to break down these by some form of manipulation. The best results, as a rule, are achieved under local anæsthesia attempting only a small amount on each occasion. If too much is attempted, as is the danger under general anæsthesia, there may be either an exacerbation of the original arthritis or extensive bruising. Both of these cause pain to the patient and make him more unwilling than ever to move the joint.

The third stage of contracture is that of bony deformity and ankylosis. If manipulation under general anæsthesia is attempted during this stage there is a serious danger of fracture of the long bones with considerable shock to the patient. So far, no effective method of treating this stage has been discovered.

Ultrasonics.—We have recently been employing ultrasonic radiations in an attempt to reverse the changes which produce contractures. This followed the demonstration by Curwen (1953) that this form of energy softened scar tissue. The machine used was the "Ultrasonar" made by Nordelectro. It had two treatment heads, one for deep treatment and the other for superficial treatment. Only the latter was used in this investigation. Our routine was to employ a dose of 5 megacycles for five minutes. Joints which were easy of access were treated by movement of the head through a film of liquid paraffin. Others, more difficult to approach, were treated through a small rubber "water bag" made from a condom. Treatment was given twice weekly to one joint at a time. After each exposure to ultrasonics, the range of movement was measured by a goniometer. In the present series, bilateral lesions were selected, so that one joint could act as control for the other.

The first patients treated by ultrasonics had advanced contractures due to rheumatoid arthritis. The results were rather disappointing. Only a very few degrees of added mobility were obtained in these cases. Further investigation showed the presence of bony deformities in the joints. It was this discovery which led to the conception of the different stages of an arthritic contracture.

Later, we selected twenty joints whose contractures were in the second stage (fibrosis). Here the results obtained were much better. As may be seen from Table I, only two joints

TABLE I.—EFFECT OF ULTRASONICS ON ARTHRITIC JOINT CONTRACTURES (GRADE 2)

failed to show an increased range of movement. Even more striking was the improved freedom of movement within that range. This was usually maintained after the cessation of treatment and did not regress in the patients whom we followed up. The additional range of joint mobility varied from 7 degrees to 33 degrees. It was usually obtained by the early treatments. After the sixth exposure, no further amelioration normally took place. In only one patient did the untreated control joint show any improvement during the experiment. All the rest showed no alteration of mobility.

On the other hand, when we studied the behaviour of neurogenic contractures, we observed an interesting phenomenon. During the actual period of treatment, the tight flexor muscles of a hemiplegic limb relaxed and the limb could be extended. Yet, five minutes after exposure to ultrasonics ceased, the muscle spasm returned and the limb resumed its contracted position. The ultimate, permanent result was little or no increase in mobility. In 3 patients with stiff painful shoulders after a cerebral thrombosis, loss of pain and increased mobility were observed. But flexion deformities of arm or leg remained only temporarily relaxed in all 15 cases of neurogenic contracture.

Up to date, we have been unable to treat any postural contractures on account of lack of co-operation by the patients.

Discussion

Since, as McEwan and Laverty (1949) showed, joint contractures are one of the common causes of the bed-fast state, it is most important to prevent them whenever possible. At present, the mechanism of the flexor hypertonus which forms their basic pathology is only imperfectly understood. But our observations described above make it clear that encouragement of extensor movements and electrical stimulation of extensor and abductor muscles can play an important role. When spasm is secondary to chronic arthritis, the use of Prostigmin injections together with physiotherapy can often prevent the stiffening which is the precursor of the second stage (fibrotic) contracture. We have also experimented with the use of Prostigmin in a vanishing-cream base, which the patients can rub in daily themselves. Our preliminary results have, on the whole, been encouraging. One or two subjects, however, complain that the use of this cream makes their gut over-active.

The results of ultrasonic radiations will need further study. Their beneficial effect upon periarticular fibrosis seems quite definite. But the unexpected temporary relaxation of hemiplegic contracture is a phenomenon of an unusual kind. No mention has been made of the pain-relieving properties of ultrasonics in certain cases since that has no connexion with joint contractures.

At present, the third stage of arthritic contractures with bony abnormalities remains unaffected by any known form of treatment. It is, therefore, important to prevent its formation by active measures in the earlier stages, otherwise these patients become exceedingly difficult to nurse effectively, and often suffer a great deal of pain.

Summary

The study of patients with contractures of their joints allows them to be divided into three separate types—those due to posture, those due to arthritis, and those due to lesions of the central nervous system.

Arthritic contractures pass through three successive stages of muscle spasm, fibrosis and bony deformity. The course, prognosis and treatment of each is discussed.

A description of the results obtained from the use of ultrasonic radiations in these conditions is given.

DISCUSSION ON HYPOTHERMIA

Dr. E. Neil (Middlesex Hospital Medical School): *Sequelæ of Circulatory Arrest during Hypothermia.*

Hypothermia is used by the cardiac surgeon so that the circulation may be interrupted for a longer period to allow operation within the dry heart. The period of circulatory arrest at 26° C. which is regarded as safe has been given as ten minutes by Swan and Ross. Most workers seem to have been preoccupied with the ability of the various vital organs to resist anoxia alone and few have paused to think of the congestive effects of complete venous occlusion for an extended period. When such congestion is associated with anoxia the effects may be serious.

One way of following the progress of an animal or a man subject to the full ritual of the hypothermic cardiac operation is to study the acid-base equilibrium. If blood is equilibrated *in vitro* at 37° C. with various CO_2 tensions the pH of the equilibrated blood can then be measured at 37° C. If the pH values obtained are plotted against the logarithm of the CO_2 tensions, the relationship is linear. If the procedure is repeated with samples of the same blood equilibrated at 26° C. and the pH values measured at 26° C., the points obtained fall on exactly the same line as before. It follows from this that if blood is removed from an animal at any stage of cooling or re-warming, this blood can be equilibrated with a series of CO_2 tensions *in vitro* and the corresponding pH values can be measured at any one temperature, say 26° C. If there has been no development of metabolic acidosis then the various blood samples removed should give the same log. pCO_2/pH graph. If there *is* metabolic acidosis, however, the log. pCO_2/pH line will be displaced to the left so that a given pCO_2 will be associated with a lower pH. We therefore used this method in experiments *in vivo*. Dogs were cooled under artificial ventilation to 26° C., their chests were opened and their venæ cavæ were occluded for ten minutes. Following this the circulation was re-established, the chest was shut and the animals were re-warmed. Blood samples were taken, before cooling, after cooling (pre-clamp samples), at the end of clamping off the circulation for ten minutes (post-clamp samples) and on completion of re-warming. All these samples were equilibrated with the series of CO_2 tensions at 26° C. and the pH of the equilibrated samples was read at this same temperature. The results of experiments on 26 dogs showed that after circulatory arrest for ten minutes the "post-clamp samples" revealed a very obvious metabolic acidosis. This "post-clamp" acidosis, revealed by the log. pCO_2/pH graph, became worse during re-warming. Similar investigations were made on patients undergoing cardiac surgery under hypothermia, thanks to the co-operation of Sir Russell Brock. In some cases gross acidosis and lactacidæmia were found on re-warming.

We attribute the derangement of acid-base equilibrium to the effects of venous congestion and anoxia during the occlusion period. The central venous pressure was measured in many of our dog experiments and on shutting off both venæ cavæ this pressure rose sharply to levels of 25 cm. H_2O or more. The high pressure was well maintained during the occlusion period. After seven minutes of circulatory arrest blood withdrawn from the venous catheter showed a negligible content of oxygen.

Liver structure was examined histologically. After cooling and re-warming (without operative intervention in the chest) the liver structure appeared virtually normal. On the other hand after cooling with circulatory arrest followed by re-establishment of the circulation and re-warming, liver structure was grossly deranged. Centrolobular necrosis with extravasation of blood was obvious. Galactose clearance studies were performed on both series of dogs. After cooling alone, galactose clearance was reduced to about a third of normal, but on re-warming the clearance recovered to 80% of its pre-cooling value. After cooling plus circulatory arrest for ten minutes, followed by re-establishment of the circulation and re-warming, the galactose clearance after re-warming showed no improvement on the rate observed when the body temperature was 26° C.

Prevention of congestion during circulatory arrest was practised in two ways in additional experiments. (1) By aspiration of blood from the inferior vena cava into a silicone reservoir. (2) By pumping the blood from the vena cava into the arteries.

By either of these methods the central venous pressure can be prevented from rising during occlusion. The results of both measures were similar. The dogs showed normal liver structure and galactose clearance after re-warming and the metabolic acidosis seen after release of the venæ cavæ almost disappeared during re-warming.

These results are presented in extenso elsewhere (Brewin *et al.*, 1955).

Dr. B. G. B. Lucas (Surgical Unit, University College Hospital Medical School, London) discussed the practical side of hypothermia, how to cool the patient, where to record the temperature, and how far the temperature should be reduced (Lucas, 1956). He said that the time available for circulatory occlusion at low temperature had not yet been established satisfactorily, but a safe guide was five minutes at 28° C., with an increase of one and one-half minutes for every further one degree fall. This factor was modified by age, and by the state of the brain and the heart immediately prior to the circulatory occlusion.

Mr. D. N. Ross (Guy's Hospital): *Problems Associated with the Use of Hypothermia in Cardiac Surgery.*

My remarks largely corroborate those of Dr. Lucas in that we have been able to use hypothermia as a safe and practical procedure without serious sequelæ such as those Dr. E. Neil has mentioned. Most of our cases have been adults; whereas Dr. B. G. B. Lucas has more experience in the younger age groups. Our experience in 70 patients subjected to hypothermia with complete arrest of the circulation for five to ten minutes has enabled us to appreciate and to eliminate many of the difficulties and dangers of the technique. The main hazard, as far as we are concerned, has been from anoxic brain damage during the period of circulatory arrest although the many alterations in physiology and the disturbing tendency of the ventricles to fibrillate have often diverted our attention from the brain. Thus we have had 26 cases of ventricular fibrillation during the cooling or intracardiac surgery with complete recovery in 21, but where we have had an absent or poor cerebral circulation for more than ten to twelve minutes there have only been 5 recoveries out of 18 cases.

The prevention of brain damage is, we believe, dependent upon the temperature to which we can cool and the period of permissible circulatory arrest at that temperature. In practice, the lowest temperature we can attain with safety is limited in our present technique by the onset of ventricular fibrillation. In dogs and in humans, there is very little tendency to ventricular arrhythmias above 28° C. although atrial fibrillation is common around 32° C. in humans. Between 28° C. and 25° C. there is a sharp increase in the incidence of ventricular arrhythmias, ectopic beats and A-V dissociation and if the heart is mechanically stimulated at these temperatures, ventricular fibrillation is likely. Below 25° C. ventricular fibrillation is very common and is likely to arise without an extraneous stimulus. Consequently we no longer cool adults below 28° C. and in children, whose hearts seem more resistant to ventricular fibrillation, we try not to cool below 26° C. (Fig. 1). Since adopting this simple policy our incidence of ventricular fibrillation during cooling has dropped precipitately.

We have given up chemicals like Prostigmin as a method of preventing fibrillation since we have not been convinced of their effectiveness. We do try, however, to minimize all forms of trauma and avoid handling the heart during the cooling. Again after the period of arrest of the circulation we are very aware of the danger of suddenly increasing the work of the anoxic myocardium and for this reason, the venæ cavæ are released slowly and in turn to allow the heart to accommodate to the increased load. We have not found any special difficulty in electrical defibrillation of the cold ventricle provided adequate cardiac massage is used to restore myocardial tone, before using the defibrillator. Too much reliance is often placed on the ability of this machine to revert the rhythm in an atonic, anoxic and poorly contracting ventricle, whereas its true function is to depolarize the well-oxygenated and vigorously-contracting heart muscle. Where defibrillation has been unsuccessful it has generally been due to serious damage to the valves or conducting bundle as a result of surgery or an inability to repair the defect.

The cause and prevention of ventricular fibrillation have received a great deal of attention in hypothermic literature and at varying times an acidosis, a rise or fall of potassium or the prolonged systolic activity phase of the cold ventricle or falling coronary circulation have been inculpated. Whatever the mechanism, we cannot escape the fact that it is the effect of cold on the active working ventricles which is ultimately responsible since it is a daily

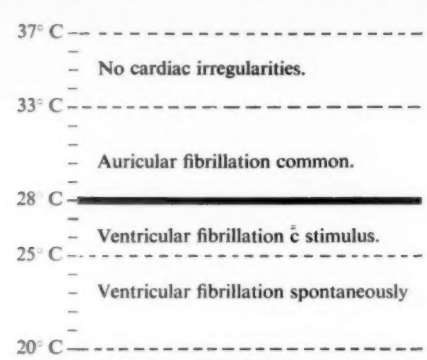

FIG. 1.—Cooling zones in relation to cardiac arrhythmias.

experience in cardiac surgery to find the heart at normal temperatures amazingly tolerant to surgical, pharmacological and metabolic insults of a very severe nature with only trivial disturbance of rhythm or function.

A feature of hypothermia which has been stressed is that while the metabolism and activity of the tissues decline steadily with cooling, the heart alone continues to contract and extract oxygen at a disproportionate rate. Also in both surface and blood-stream cooling methods, it is the active heart which is likely to be the coldest organ in the body since it is required to distribute the cold blood coming from the surface tissues or cooling coil to the deep tissues and brain. Consequently the heart is both the most active tissue and at the same time the coldest. We can separate these factors of activity and cold by inducing hypothermia with the aid of a heart-lung circuit so that the heart is relieved of its work load. Under these circumstances the heart slows progressively and is arrested in asystole at about 14° C. without passing through a phase of ventricular fibrillation. The heart is then cooled via its arterial supply to very low temperatures and this is achieved by permitting its work to decline like the rest of the body with falling temperature. Hypothermia has been induced in this way by Gollan *et al.* (1955) with the aid of a simple heart-lung machine and temperatures of 0° C. have been reached with recovery. However, the problems associated with artificial pumps and oxygenators at present outweigh the advantages of this theoretically ideal cooling technique. When it can be applied with safety it will permit very rapid cooling to much lower temperatures with correspondingly longer periods of time available for intracardiac surgery. Also these low temperatures will confer the advantage of an arrested and quiescent heart.

The permissible period of total arrest of the circulation under hypothermia.—We are, at present, limited here by the time we can safely exclude the brain at our working temperature of 28° C. Oxygen consumption studies and experimental observations in dogs suggested a safe period of occlusion of at least fifteen minutes at 25° C. and at 28° C. we have allowed ourselves a maximum of ten minutes of circulatory arrest with about eight minutes of intracardiac surgery. This has proved safe in practice and although we have had complete recovery in an adult woman who had her circulation arrested for thirteen minutes at 28° C., there was definite evidence of disturbed cerebration for forty-eight hours post-operatively. Signs of anoxic brain damage in the post-operative period have been an initial difficulty in re-warming followed by hyperpyrexia and a cold pallor of the skin associated with fixed dilated pupils. These patients have never recovered. Milder signs have been a delay in coming round from the anæsthetic, restlessness and a sharp rise of temperature to 103–104° F. In these cases we have taken precautions to limit fluids, particularly blood replacement, and we have occasionally given hypertonic solutions, in addition. In fact we aim to undertransfuse in all cases. Evidence of brain damage is not seen in cases which are cooled to 28° C. and have less than ten minutes of circulatory arrest. These cases come round from the anæsthetic promptly and often while the body temperature is still about 33° to 34° C. Also there is generally no post-operative rise of temperature.

The eight minutes of intracardiac surgery limits us in the type of intracardiac defect in which we can hope to achieve repair. Straightforward defects of the atrial septum fall into this category and also pulmonary valvular and infundibular stenosis and more recently aortic valve stenosis. Ventricular septal defects including Fallot's tetralogy and the ostium primum type of atrial septal defect are not suitable for closure by present techniques; not because they may necessitate an incision in the ventricle—for ventricular incisions can

be well tolerated in hypothermia—but because at least twenty minutes of unhurried cardiac surgery are required for their definitive closure.

A difficulty we have encountered with the venous blood-stream cooling technique has arisen as a result of the very rapid cooling rate we have been able to achieve especially in small children. Unless the rate of cooling is deliberately kept within certain limits, uneven cooling of the body will result in very low heart temperatures and the danger of ventricular fibrillation before the mass of the brain has cooled evenly. For this reason we aim to cool at a rate of not more than 1° C in four minutes for children and infants below 26 kg. making a total cooling time of about thirty-six minutes. The cooling rate is charted at five-minute intervals during the lowering of temperature so that adjustments can be made to keep the rate of fall approximately along a predetermined line on the graph. Adults generally cool at a rate of 1° C in six to eight minutes with a cooling time of about forty-five minutes. Too rapid a cooling rate is also reflected in the ECG picture which shows atrial fibrillation and A-V conduction disturbances. An ominous development has been an increased notching and slurring of the Q.R.S. The interpretation of this phenomenon is under debate but it often precedes the development of ventricular fibrillation.

We have found the blood-stream method of cooling has great advantages in cardiac surgery, particularly in allowing us to manipulate the heart freely and to take pressure measurements and explore the interior of the atria digitally at normal temperature and when the heart is not irritable. This ability to make a final diagnostic assessment at operation will assume increasing importance when we have a heart-lung by-pass available. A choice of either hypothermia or the artificial heart lung will then be applied to meet the appropriate needs of the intracardiac defect.

Difficulties which we had anticipated as arising from altered or disordered metabolism have not constituted a problem in clinical practice. We aim to keep the respiratory acidosis at a minimum by the anæsthetist maintaining a more than average respiratory exchange throughout the hypothermic period without sudden bursts of hyperventilation—as has been advocated by some workers. For the rest, we feel that the total time during which the body is subjected to a low temperature is important. This is achieved by rapid cooling followed by rapid blood-stream re-warming. Once the temperature is restored to normal, we assume that the kidneys and liver will again be able to make good any biochemical disturbances that may have developed and our cases now have the same pre- and post-operative management as any major chest operation.

Dr. H. H. Khalil (University Hospital, Alexandria, Egypt) described results obtained using the intra-gastric balloon (Khalil and Mac Keith, 1954) for producing hypothermia by internal cooling. He described a machine for continuous controlled perfusion of cold water. The rate of production of hypothermia was controlled by the rate of flow of coolant into the intra-gastric balloon. The degree of distension of the stomach by the balloon was under continuous observation in preliminary experiments.

In preliminary experiments at Guy's Hospital in 1954, using this method he had lowered the temperature of rabbits from 39° C. to 20° C. and the heart beat had slowed to 60 beats a minute. Later the method had been used in a case of hyperpyrexia in a child (Khalil and Mac Keith, 1954).

Dr. Khalil described a further series of experiments on dogs under anæsthesia and cooled by continuous flow through the balloon of two litres per minute of water at a temperature of 4° to 5° C. This gave lowering of the body temperature to between 23°–26° C. rectal temperature. The time taken for this cooling was about two and a half hours. Shivering was prevented by the animals being under ether anæsthesia. After cooling was stopped, there was a further drop in rectal temperature and heart-rate. When no warming was applied animals cooled only to 25° C. warmed much more rapidly than those who had been cooled to 23·2° C. Recovery could be accelerated by circulating warm water. There were no signs of permanent damage from these procedures which probably act mainly by slight cooling of a large volume of blood circulating in the great vessels of the abdomen.

In contrast to the results described by Mr. D. N. Ross and illustrated by his Fig. 1, Dr. Khalil had found that after internal cooling, arrhythmias were rare even at 23° C., the injury potential described (Osborne, 1953) as precursor to ventricular fibrillation appeared in only 4 cases out of 16, and ventricular fibrillation did not occur at all.

Internal cooling by the intra-gastric balloon is an efficient and a safe technique.

Twenty Years of Leucotomy

By WALTER FREEMAN, M.D., Ph.D.

Formerly Professor of Neurology, George Washington University, Washington, D.C.

EGAS MONIZ died a year ago at the ripe age of 81. He lived to see one of his major discoveries, angiography, universally adopted and the other, leucotomy, still in vigorous dispute. Fulton, Tow and others have told how the idea of leucotomy germinated here in London. At the Second International Neurological Congress in 1935 the session on the frontal lobes brought forth a number of reports of the harmful effects of traumatic and neoplastic lesions upon personality. Moniz, having already pondered the neurology of obsessive thinking, was the only one present who saw through these damaging effects to their possible benefit in cases of functional mental disorder. A year after the Congress he reported twenty leucotomized patients; one-third recovered, one-third improved and one-third unchanged. It is remarkable that over the past twenty years the proportion of good results has remained much the same.

The work was taken up, on a small scale at first, in Cuba, Brazil and Italy. In the United States it took Freeman and Watts five years to collect the first hundred cases. It may be recalled that the various shock therapies were flourishing in this same five-year period. The Board of Control assembled 1,000 leucotomy cases in 1947. The U.S. Public Health Service survey in 1951 counted 18,600 psychosurgical cases covering the fifteen-year period. Was this an unhealthy growth? In the years 1949–1951, according to the survey, the leucotomy rate in the U.S. was 6·5 per 1,000 average daily resident patient population. Unoperated patients, therefore, averaged 993·5 per thousand. At this rate it would take some 150 years to apply leucotomy to everybody, not to mention later arrivals. Leucotomy has been applied, it would seem, on a rather modest scale. Recently interest has veered to the tranquillizing drugs. It may be several years before the proper indications for leucotomy are fully established. Meanwhile it may be of value to review the twenty years of leucotomy in an effort to determine the place that it deserves in psychiatric therapy.

INDICATIONS AND CONTRA-INDICATIONS

Leucotomy achieves its most satisfactory results in patients who are distressed by feelings of anxiety, obsessive thinking and what may be termed anguish or tortured self-concern. The operation reduces the emotional tension to a point where it no longer disables the patient. The list of disorders for which it has been successfully employed is a long one,

and embraces not only certain psychoses and psychoneuroses, but also psychosomatic disorders and pain syndromes that can be relieved in no other way.

Heightened emotional tension is a *sine qua non* for success in leucotomy. Patients who have given up the struggle, who accept their symptoms as part of themselves, or who take refuge in alcohol or drugs are generally poor prospects for surgery. On the basis of several hundred assorted patients Watts and I concluded that a deteriorated schizophrenic looks and acts the same with or without his frontal lobes.

Experience has shown that leucotomy may be socially dangerous in patients with aggressive antisocial traits. There may be a difference between those who offend against property such as forgers, burglars and thieves as opposed to those who offend against persons. The almost complete absence of sex crimes by leucotomized patients is noteworthy. However, the time has not yet come when leucotomy can be recommended in the treatment of the sexual offender. Patients who commit crimes of violence under the influence of a psychosis are often favourable candidates. In another direction, leucotomy is to be undertaken with reluctance in patients with superior intellectual and social accomplishments. Artists, musicians, physicians, writers and ministers may lose some of their inspirational value as the result of their mental disorder combined with leucotomy.

When the pros and cons of leucotomy are being weighed in connexion with any given patient, the question must arise as to the possible damaging effect upon the personality, of the operation itself.

Is Leucotomy Harmful?

All but the strong proponents of the various psychosurgical operations will answer "yes". Theoretical considerations should make it so, since it is difficult to see how mutilation of the brain can make for better functioning. Even the proponents of operation are sometimes hesitant and apologetic about it, since they have seen many patients who, while being able to live more comfortably after operation, have nevertheless suffered some loss in depth of personality, some blunting of their creativeness, some decrease in sensitivity and empathy, some reduction in altruism, fervour, zeal or spiritual quality that they possessed at one time in their lives. These personality alterations are found so frequently in the run-of-the-mill patients after leucotomy that it has been rather widely accepted that the operated patient is different from his former self, and that, while he is able to live with himself and with others on a better plane than he could before he was operated upon, yet the intrusion of the mental illness plus the leucotomy has taken something away from him, something that was highly desirable as a social trait.

Psychiatrists who have carefully followed their patients over long periods can select a few who seem altogether unharmed by the operation and who manifest social poise, ambition, creativeness, executive capacity and altruism to a degree at least equal to their premorbid level. In fact, these patients accomplish more than might be expected precisely because they have been freed by operation from the burden of painful self-consciousness and sensitivity to criticism. They are able to direct their talents into productive fields beyond what had been possible for them before they fell ill. What they have lost through operation is the restraining drag of diffidence, the realization of the spread between ambition and accomplishment, and the hesitancy to undertake some constructive effort for fear of failure that would injure their self-esteem. The illness that led to disability and eventually to operation seems like an incident in the remote past. After convalescence they take up their lives as though the illness had never existed. They can even experience the same symptoms that they did during their illness, but no longer to the degree of ruminative incapacity.

Leucotomy does not necessarily interfere with progressive development of the patient's personality into a more mature and wholesome state. When the constructive aspects of the personality are overwhelmed by a disabling neurosis or psychosis, leucotomy can be undertaken with confidence that it will restore to the suffering patient the equanimity that is essential for further growth.

Five, Ten and Fifteen Years Post-leucotomy

The importance of long-range follow-up was stressed by Adolf Meyer on the occasion of the first presentation of the subject made by Watts and me in the fall of 1936. At that time we reported 6 cases operated upon within the preceding two months. Fortunately our selection was such that twenty years later we could say that 4 were successful. Had we selected a series of schizophrenic rather than mostly involutional or psychoneurotic patients

it seems likely that the question of leucotomy would then and there have been answered unfavourably.

From these 6 patients, the series grew to more than 600. All of the survivors have been traced for at least five years, and many of them for over ten years. Social effectiveness was chosen as the criterion of success. Patients were graded at various periods after operation, namely, employed, keeping house, home, hospital.

It requires about two years for the patient to become stabilized after prefrontal leucotomy. It is at this time that the patients who relapse are about balanced by those who improve slowly. Thereafter, for a period of many years there is substantial stabilization. This is shown in Table I.

TABLE I.—STATUS OF SURVIVING PRIVATE PATIENTS AFTER PREFRONTAL LEUCOTOMY

Diagnosis	Number	Employed %	Keeping house %	Home %	Hospital %
Schizophrenias

15 yrs.	22	45	18	32	5

Similar stabilization is also noted in studies from the Boston Psychopathic Hospital, where the five-year results are rather better than those at the end of one year.

Comparison of patients operated upon as private patients and those operated upon in a public mental hospital (in this series, St. Elizabeth's Hospital), shows an immediate and striking difference. The number in the Freeman-Watts series is rather small, numbering 60 patients, and made up mostly of schizophrenics. Of the total number, 35% of the men and 45% of the women were out of the hospital for a period of more than six months. Detailed breakdown of figures is not worth while on such a small material but among schizophrenic patients, at least, there is a great difference, 60% remaining in the hospital as opposed to 30% of the private patients.

While the St. Elizabeth's patients were hospitalized longer on the average (6·5 years versus 3·5 years for the private patients), the support given by the family must be considered as of equal or greater importance in the outcome.

One of the controversial aspects of leucotomy is the question of when to perform the operation. There has been so much fear of producing unfavourable personality changes through operation that this is delayed until other methods can be thoroughly tested. This fear was only too well realized in the earlier years of the leucotomy research, but it seems adequately proven by this time that operation on the frontal lobes is not necessarily damaging to the personality.

Therefore, among the hazards of leucotomy, the greatest, in my opinion, is the hazard of delay. In speaking of topectomy and other psychosurgical operations less radical than standard leucotomy, Hoch and his collaborators have recently stated that: "The surgery need not be viewed as a desperate last resort after all possible measures of doubtful effectiveness or of known ineffectiveness have been tried. . . . An excellent therapeutic response may be obtained without the complication of undesirable personality change."

Granting the hesitancy to recommend leucotomy in a patient who is still functioning reasonably well, there are some clear indications for surgery: (i) First of all, I would place *relapse into disability*. There may be extenuating circumstances such as extreme external pressures that contributed to the relapse, and the psychiatrist is justified in repeating the treatment that previously aided the natural restorative powers of the patient. But relapse

shows that the patient is poorly armed to withstand the normal experiences of existence. Furthermore, repeated relapses are apt to lead to scarring of the personality that is even more serious than the mild effects of a leucotomy carried out conservatively before deterioration becomes noticeable.

(ii) The second indication for operation in my estimation is the *duration of the attack*. It is known that some patients can make an apparently perfect recovery after years of psychosis, but the number is small. On the basis of 25,000 first admissions, Malzberg states: "It is evident that the chance of discharge declines rapidly after two years of hospitalization." Granted that early treatment can restore a good 60% of patients (although relapses are threatened), there is another 40% of first admissions that do not stay well. It seems preferable to operate upon the patient who has shown unsatisfactory progress in the second six months, and take the small chance on something going wrong, rather than wait out the full two-year period.

Leucotomy and the State Mental Hospital

Duration of hospitalization is a factor of major importance in the outcome of leucotomy. Yet there are few data upon patients leucotomized after less than two years of hospitalization. When it is further considered that patients who enter state hospitals have already been treated on the outside until their disordered behaviour makes it necessary to send them to hospitals, it may be concluded that most of these patients are already in the chronic stage of illness. Review of their histories discloses an abundance of treatment for supposed physical complaints such as anæmia, back-strain, uterine retroversion, dyspepsia, and a variety of other manifestations that might well have been recognized as psychically determined years before the breakdown became evident. In various tabulations I have concentrated upon the time factor: *duration of symptoms*, *duration of disability* and *duration of hospitalization*. Of these three, the duration of hospitalization is the most important (Table II).

Table II.—Status of Survivors One Year after Transorbital Leucotomy Compared with Duration of Hospitalization before Leucotomy

Duration of Hospitalization	Number	Percentage released
None	22	77
Less than 6 months ..	88	82
6 months to 1 year ..	119	64
1 year to 2 years ..	176	52
2–3 years	173	44
3–4 years	97	39
4–5 years	92	28
5–10 years	289	26
10–44 years	320	12

I recently completed a study of patients operated upon by me in a number of state mental hospitals in different parts of the U.S. The release rate in these hospitals ranged from 0 to 91%. There were two hospitals where leucotomy was undertaken within one year, when other methods had failed. The release rates were 88% and 91%. Operation in the second year produced 60% releases. At the end of four years the figure was around 40%. It appears from these figures that early operation is justified. During the second year of hospitalization valuable time is being lost. If more conservative treatment is not producing results at the end of one year, it appears to me that operation gives the patient a greater chance of release than he will ever have again.

The West Virginia Lobotomy Project was undertaken in 1952 and continued during the succeeding two years. West Virginia is a mountain state with forests, mines and small farms, and some notable heavy industries. The state hospitals are above average in crowding. During the period of three years 744 patients were operated upon with a discharge rate of 36%. Based upon a *per diem* rate of $1.94, this represented a saving to the state of $337,000 (Table III). Of course, this was only a paper figure since, as Nature abhors a vacuum, the hospital population showed no decrease but, at least, other patients who needed treatment could be admitted to hospitals. During the first year there was a control group of 202 patients whose families refused permission for operation. At the end of one year 5 of these patients had left the hospital and 2 had died. Of the 228 patients operated upon in 1952, 85 left the hospital and 4 died. Of those discharged, the few who were employed had cash earnings exceeding the cost to the state of the whole project.

TABLE III.—WEST VIRGINIA LOBOTOMY PROJECT REPORT—JUNE 30, 1955
Transorbital Lobotomy Operations 1952, 1953, 1954

	Weston	Huntington Barboursville	Spencer	Lakin	Total
Number of patients operated on	222	153	225	144	744
Number released from hospital and still out	60	45	105	58	268
Improved sufficient for release but no home	9	0	6	62	77
Improved, but not sufficient to go home	29	46	19	18	112
Mental condition worse	31	2	6	0	39
Condition unimproved	84	53	87	3	227
Deaths	9	7	2	3	21
Patient-days saved	33,478	34,549	63,065	42,641	173,733
Budgetary savings	$56,243.04	$64,304.13	$111,163.13	$105,457.58	$337,167.88

And this did not include patients who were working on family farms, or keeping house, or otherwise usefully occupied.

It appears, then, that leucotomy can bring about release from the hospital of a considerable number of patients who can return to their homes and work productively.

The gain to the individual from leucotomy has to be considered in terms of relief of suffering, of restoration to productive existence, and to enhanced self-esteem. On all these counts leucotomy has accomplished more in a short time than any other therapeutic endeavour. It was also shown in this study that leucotomy by the transorbital route could be carried out in a situation marked by shortage of everything except patients.

These results are by no means unique. Transorbital leucotomy has been carried out in other state hospitals by Wilson *et al.*, by Moore, and by Jackson and Jako, all of them psychiatrists, upon more than 400 patients each, and with similar statistics. Substantially, they have found that transorbital leucotomy is a safe procedure to carry out in an institutional setting, that an over-all release rate of 35% is attained, and that the earlier a patient is operated upon the greater the chance of his being able to leave the hospital. The reduction of disturbed behaviour in those remaining in the hospital is frequently gratifying. Therefore, in spite of the offensiveness of transorbital leucotomy to the æsthetic sense of the surgeon, this operation offers much to patients and their families who would otherwise be denied a better chance for recovery and reunion.

There is also something to be said on the effect of long hospitalization upon the morale of the family. While the patient is at first in the hospital and undergoing treatments that have a good chance of restoring him to the family circle, the interest of the family is maintained on a high plane. When chronicity develops, the family attitude changes, the broken ranks are closed and the family goes ahead without the patient. At a much later date, should the patient be physically and mentally fit to resume family life, it is found all too often that there is no longer a place for the patient. The children have grown up, or the family has moved or split up, and the problem of his reintegration into the family circle has become more than a remote hazard. The best time to operate is during the first year, and the best time for release after operation is at the end of surgical convalescence. Then the patient and the family can get back to their readjustment problems in a more wholesome manner, and mutually obtain satisfaction in life together. Leucotomy can contribute notably to the morale of the whole family.

PSYCHOSOMATIC DISORDERS, TUBERCULOSIS, PAIN

(i) *Psychosomatic disorders* have been studied particularly by English authors, and a number of remarkable cures reported. The outstanding condition seems to be ulcerative colitis, but anorexia nervosa, Raynaud's disease, eczema, arthritis, spastic colon and many others have also yielded to leucotomy when medical and surgical measures have previously failed. The symptoms of hypertension are more likely to be benefited than are the blood pressure levels, but a decline in blood pressure in the middle-aged involutional depressive has often been witnessed, and this decline may last for a decade. Asthmatic states are less likely to be affected, and I have seen some instances in which asthmatic attacks have occurred for the first time following leucotomy. Peptic ulcer has been noted following operation, even with perforation, but in patients experiencing intractable pain its relief may be associated with healing of the ulcer. Leucotomy relieves preoccupation with the self and permits the organism to undertake the necessary repair.

(ii) Cheng, Tait and I have recently reported upon the beneficial effects of leucotomy in a series of 57 *psychotic tuberculous patients*. Not only did the patients gain weight and lose their fever, but the sputum became negative and the cavities tended to heal. Leucotomy permitted the patient to rest and to eat, and to accept treatment without the usual psychotic refusal to co-operate. Tuberculosis in a psychotic individual seems to be a strong indication for leucotomy if the course is downward in spite of medical and surgical therapy.

(iii) *Leucotomy in the patient who is experiencing intractable pain* is a knotty problem. Ten years ago Watts and I (Freeman, W., and Watts, J. W., 1946, *Proc. R. Soc. Med.*, **39**, 445) reported some cases before this Society. Further studies have shown that best results are obtained in patients who are emotionally upset by the pain, who require large to massive doses of opiates, and who do not have very long to live. Leucotomy, as Scarff has said, offers a relative barrier to pain. With the extension of the disease process and involvement of other areas, the relief experienced during the early post-operative period tends to disappear. Since the relief may last for from six to nine months, however, the cancerous individual may not survive to experience the recurrence of pain to the former extent. It has been noted that patients with such intractable pain are relieved of their suffering, rather than of the pain itself. Suffering, therefore, may be considered the emotional component of a painful disorder. Furthermore, the pain experienced by these subjects is often of low intensity, in spite of the complaints. If one is to judge of the intensity of the pain which the patient suffers, a good test is to bend the fingers of the patient until the pain in the fingers is worse than the pain in the diseased area. Furthermore, pain of high intensity, such as that due to movement of a collapsed vertebral body, is of short duration and elicits an agonized response from the patient, however extensive his leucotomy may have been. Pain of high intensity is truly unbearable and will throw the patient into shock if long continued. With the suffering of the cancerous patient modified, the patient will often rest more adequately and actually gain weight and strength for a while until the malignant process produces the terminal cachexia.

Non-malignant processes that produce considerable suffering, such as causalgia, phantom limb, tabes dorsalis and post-herpetic neuralgia, are less satisfactorily influenced by leucotomy. In order to be effective for long periods, the leucotomy has to be so extensive that the personality of the patient is adversely affected. This has given rise to a reaction against leucotomy in the treatment of painful conditions. The modified operations are not always successful and the radical operations are disastrous. When the surgeon finds himself in this dilemma, he is justified in his hesitancy to perform any leucotomy.

DISCUSSION ON THE NEURO-OPHTHALMOLOGICAL ASPECTS OF THE CEREBRAL ANGIOMAS

Dr. Helen Dimsdale: The angiomas are now regarded as relatively common intracranial lesions and the importance of their early diagnosis to facilitate surgical treatment has been stressed in a recent paper by Paterson and McKissock (1956), total excision being possible in about one-third of their cases. Although the territory of the middle cerebral artery is the usual situation for vascular malformations, they also commonly occur in the posterior region of the hemisphere where the posterior cerebral circulation is chiefly concerned in their supply. The clinical features of the subtentorial or posterior fossa angiomas which involve the cerebellum and brain-stem have been described by Logue and Monckton (1954), and Paterson (1955) has described the central angiomas which include those invading the mid-brain. Apart from the orbital angiomas which are rare, it is those angiomas occurring in the posterior part of the hemisphere and in the brain-stem which, due to their anatomical location, are prone to present with ophthalmological manifestations.

Their nature is generally accepted as being that of a vascular malformation of congenital origin. Other synonyms used to describe them include arteriovenous malformations, hæmartomas, and perhaps less correctly, arteriovenous and cirsoid aneurysms. Telangiectatic and cavernous forms occur but in this paper the arteriovenous anomalies will be considered.

The superficial angioma is visible as a mass of vessels in the meninges and on the surface of the hemisphere and may be observed in section to penetrate into the brain substance, tapering towards the ventricle. When deeply situated no abnormality is evident on inspection of the meninges and cortex. The lesion consists of abnormally large and tortuous vascular channels which may have the structure of arteries or veins but frequently show an indeterminate histology. Degenerative changes are common in the vessel walls with calcification which may be evident on straight X-ray examination.

The malformation is capable of increase in size by distension of the abnormal vessels, formation of aneurysm dilatations, and—due to the pressure of the arteriovenous shunt—small vascular channels in the neighbourhood enlarge. Episodes of hæmorrhage with clot formation may cause a sudden expansion. The presence of cerebral tissue between the vessels and their adult structure differentiates the angioma from the capillary hæmangioblastoma which is a true tumour, a distinction stressed by Cushing and Bailey (1928) and supported by Professor Russell (1950). The latter is composed of solid masses of angioblastic endothelial cells which form capillary channels, or liquefy, as in the cerebellum, to produce a cyst with a proliferating mural nodule. As a rare phenomenon the hæmangioblastoma may be associated with congenital cysts in the viscera and angiomatosis retinæ, comprising Lindau's syndrome.

The congenitally installed association in Sturge-Weber's syndrome of trigeminal port-wine nævus, buphthalmos and contralateral hemiplegia with focal fits, has an intracranial component of a leptomeningeal venous nævus and underlying cerebral atrophy. Sturge-Weber's syndrome links up with other malformations and dysplasias, including the phakomatoses.

Cerebral arteriovenous malformations may be associated with excessive vascularity of the scalp, minor capillary angiomas of the skin and abnormalities in formation of the retinal vessels described in the Continental literature as cirsoid aneurysms, but such multiple manifestations are uncommon.

Clinical Features

The material for this paper is drawn from a series of 50 patients, for which I am much indebted to my colleagues at the Maida Vale Hospital for Nervous Diseases, and, in particular, to Mr. Valentine Logue for his surgical records.

The sex incidence showed no significant difference, the age of onset of symptoms varied from 6 to 65, with the third and fourth as the commonest decades, the diagnosis being made on an average about a decade later (Table I). The symptomatology of the angiomas has been fully described by Northfield (1940–41), Mackenzie (1953) and Paterson and McKissock (1956). The cardinal symptoms consist of epilepsy, hæmorrhage, subarachnoid or intracerebral, and periodic headache, the relative incidence of the first two symptoms varying in

TABLE I.—AGE OF ONSET OF INITIAL SYMPTOM

Years	No.	Per cent	Years	No.	Per cent
0–10	5	10	41–50	8	16

21–30	11	22	61–70	1	2
31–40	12	24			

different series. In the present cases epilepsy was the commonest symptom but periodic headache occurred in 26%. In half the cases hæmorrhage was the diagnostic symptom. Progressive focal signs, notably a hemiplegia, are an uncommon mode of onset (Table II).

TABLE II

Initial Symptoms	Number	Percentage
Epilepsy	17	34
Hæmorrhage ..	15	30
Headache	13	26
Focal symptoms ..	3	6
Subjective bruit ..	2	4
Diagnostic Symptom		
Hæmorrhage ..	25	50

TABLE III

Site	Number	Percentage
Hemisphere:		
Posterior (Occipital, Occipito-parietal, Occipito-temporal)	15	30
Middle	16	32
Anterior	9	18
Central	5	10
Orbital	1	2
Posterior fossa ..	4	8

The symptomatology depends in part on anatomical location and the patients under review will be considered from this aspect (Table III).

Posterior hemisphere angiomas.—The hemisphere lesions provided 15 posteriorly situated angiomas, 11 receiving their vascular supply chiefly from the posterior cerebral artery.

The principal symptom of angiomas in this region was periodic migrainous headache, starting in adolescence and early adult life, and present sometimes as long as thirty years before a hæmorrhage or focal signs resulted in the patient being referred to hospital.

Sir Stewart Duke-Elder (1949), quoting Liveing (1873), has classified the manifestations of migraine into four types: (1) Simple hemicranial headache, (2) sick headache, (3) blind headache in which visual phenomena figure largely, and (4) those in which the manifestations indicate a wider involvement of the sensorium. All four types were represented but the commonest manifestation was blind headache associated usually with an angioma supplied by the posterior cerebral artery.

The following patient is an example of migraine as the sole symptom of an angioma:

Case I.—A woman aged 27 complained of recurrent left-sided headaches for the past eight years which were preceded by flickering lights in the right homonymous half-fields. The visual disturbance lasted about twenty minutes and was followed by a severe left-sided headache, frequently of a throbbing character, exacerbated by moving and coughing, and associated with vomiting. On one occasion she experienced a slight patch of dimness in the right side of her fields of vision which persisted for some hours, but then cleared up.

The only abnormality detected on examination was a faint bruit over the left internal carotid artery. Angiography revealed a large angioma in the left occipital region which was supplied by two branches from the posterior cerebral artery (Fig. 1). Operation was decided against as she

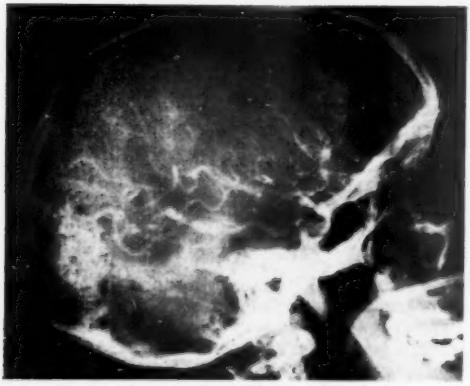

FIG. 1 (*Case I*).—Lateral view of angioma.

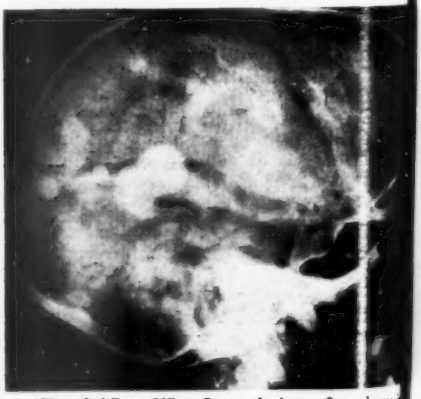

FIG. 2 (*Case III*).—Lateral view of an ioma the venous phase.

had no visual field defect and in addition had experienced no hæmorrhage. The fact that the disturbance always appeared on the same side was perhaps the only point in the history which might have made one suspicious that her migraine was, in fact, symptomatic. Incidentally she has obtained relief with ergotamine tartrate, which is not uncommonly experienced by patients with headaches due to vascular malformation.

Posteriorly situated lesions differ from those elsewhere in the hemisphere in that epilepsy is a less common symptom. Only 4 patients had experienced epileptic attacks which were infrequent and in one restricted to childhood.

Case II.—One patient, a man aged 43, gave the history of a combination of epileptic and migrainous attacks. His fits started at the age of 10, and were preceded by an aura of something passing across his fields of vision from right to left, and objects in his left visual fields appeared "strange". He then experienced left-sided tingling and a noise like a dynamo in his head for half an hour, after which he became unconscious and had a generalized convulsion. At the age of 33 migraine predominated with a left hemianopic onset, and flashing lights synchronous with his heart beat in the blind half-fields, a distinguishing feature from idiopathic migraine in which according to Butler (1941) the rate of flicker in the visual fields is equal to alpha rhythm. Ultimately this patient developed a left lower homonymous quadrantic field defect, and angiography revealed a large right parieto-occipital angioma.

Hæmorrhage was the reason for investigation in 10 patients. Bleeding due to an angioma, particularly if superficially placed, appears less catastrophic than that due to an intracranial aneurysm, and a patient may survive several subarachnoid hæmorrhages.

The usual focal result of a bleed from an angioma in this region is the appearance of a persistent homonymous field defect but in one patient an attention defect resulted. A troublesome feature which may follow on recovery from a subarachnoid hæmorrhage is the development of persistent headache in addition to the periodic exacerbation.

The sudden development of focal signs may occur without evidence of a hæmorrhage and is due perhaps to a sudden dilatation of an angiomatous coil of vessels.

Case III.—An accountant, aged 53, had experienced periodic frontal headaches for twenty years, with photophobia. When adding up his bridge score in a hot room he developed a headache and suddenly found that he was unable to calculate. During the course of the next few days he noticed that he could not see objects on his right side, that he had difficulty in reading and tended to use words incorrectly. He also was troubled by a rushing noise in his head. He showed a right homonymous hemianopia sparing fixation, alexia, and a partial Gerstmann's syndrome consisting of confusion of his right and left, inability to select and recognize individual fingers when looking at both hands, and difficulty in calculation. There was a loud systolic bruit audible on auscultation of the skull in the left mastoid region. Angiography confirmed the presence of an angiomatous malformation with huge venous channels in the left occipito-parietal region supplied by both meningeal and occipital arteries, and by the right vertebral artery (Fig. 2). This mass of vessels had presumably interfered with cerebral function in the region of the left angular gyrus.

Surgical treatment consisted of ligation of the left common carotid and both occipital arteries, and since that time he has been well. The focal signs with the exception of the bruit and field defect cleared. He still has occasional headaches under stress, relieved by phenobarbitone.

Abnormalities of the fundi were not observed except for papillœdema in one patient with focal signs, which persisted after removal of the occipital angioma.

What features in a history of periodic migrainous headache would make one suspect the presence of an angioma? Chiefly the persistent lateralization of the headache to one side, though generalized headache may occur. A family history of migraine or its absence does not assist the diagnosis. Such a history was absent in these cases but Paterson and McKissock (1956) in a larger group, considered that their patients presenting with periodic migrainous headache had a higher family incidence of migraine than a control group. There may also be a history of an episode of acute exacerbation of headache which confined the patient to bed, or even of an attack of "meningitis" followed perhaps by a persistent field defect. A cranial bruit is a valuable sign in adults, frequently audible in the carotid triangle or mastoid region, and occurred in about half the patients with occipital angiomas. Homolateral facial telangiectasis of a minor character was observed in only one patient.

The middle group of hemisphere angiomas which include Sylvian and temporal lesions, usually presented with epileptic attacks or less commonly a hæmorrhage, often intracerebral and producing lesions of the optic radiation.

Case IV.—Intracerebral bleeding into the right temporal lobe in one woman aged 59 produced a homolateral III nerve palsy, possibly due to compression of the nerve against the peduncle, a quadriplegia maximal on the left, and a left homonymous hemianopia. In spite of her grave condition, she made a complete recovery following evacuation of blood and excision of the angioma.

The anterior or fronto-parietal angiomas provided 18% of cases. Headache was not a common complaint but epileptic attacks occurred in every patient except 3 when a hæmorrhage was the first indication of the presence of a vascular abnormality.

Case V.—One patient with a large left frontal-parietal angioma and a right hemiplegia showed a facial spider nævus on the bridge of the nose. He also had a variable proptosis on the side of the lesion which may have been responsible for his complaint of fluctuating diplopia, and a frontal bruit.

The central angiomas have been defined by Paterson (1955) as arteriovenous malformations situated in the thalamus, basal ganglia, internal capsule and mid-brain. The majority of his series of 9 presented with a contralateral hemiplegia of slow or rapid onset and with sensory loss and in some patients a partial or complete homonymous defect. Episodes of hæmorrhage might occur and rarely fits; migrainous headaches were not a symptom. Mid-brain disturbances were observed consisting of weakness of vertical gaze, pupillary abnormalities, nystagmus, external ocular palsies and ptosis.

Similar ocular disturbances with long tract signs were described by Wyburn-Mason (1943) in a series of mid-brain vascular malformations entitled arteriovenous aneurysms, which were unusual in the high incidence of congenital anomalies of the retinal vessels and trigeminal facial nævi.

The central angiomas in the present series showed an incidence of about 10%. There was a marked variation of age of onset of symptoms from 6–43 years of age The usual mode of presentation was a progressive hemiparesis or ataxia of the contralateral limbs. This might be associated with a homonymous hemianopia, presumably due to involvement of the optic radiation, as in one woman aged 21 with a history of left-sided migrainous headache since the age of 16, in whom angiography revealed an angioma situated behind the sella in the left basal ganglia region.

Posterior fossa angiomas.—Both the cerebellar angiomatous malformations described by Logue and Monckton (1954) produced symptoms of an apoplectic onset with headache or confusion, dysarthria, cerebellar signs, and diplopia due to an external rectus paresis with nystagmus in one case.

The brain-stem group, which, unfortunately, are less amenable to treatment than supratentorial lesions, are ophthalmologically interesting because although they may present with a subarachnoid hæmorrhage, in some the onset may be insidious and the picture one of progressive focal symptoms with ocular palsies. The brain-stem angiomas extend along the floor of the third ventricle to the pons and fourth ventricle. The collection of abnormal vessels are inextricably interwoven with the brain-stem and may cause displacement of the aqueduct and 4th ventricle backwards, resulting in internal hydrocephalus.

Signs of III and VI nerve involvement appear combined with other cranial nerve palsies, cerebellar ataxia and long tract signs, which may be unilateral or bilateral and show an intermittent progression for as long as fifteen years.

In those with a long history, disseminated sclerosis requires distinction, and the absence of any story of retrobulbar neuritis is helpful. Headache also is more prominent. Glioma of the pons has a more rapidly progressive course. Myasthenia gravis may be suspected due to the fluctuating course, but the palsies do not respond to neostigmine. A bruit may be audible in the posterior occipital region, and characteristic changes in the X-rays of the skull which have been described by Sutton (1952).

The general circulatory effects of an angioma tend to occur when the lesion is large, with a big arteriovenous shunt which has been present for a number of years. There may be cardiac hypertrophy and an increased pulse pressure. The presence of a free arteriovenous shunt with cerebral atrophy due to ischæmia may produce some degree of dementia.

I have only observed this in one patient, a woman aged 59, with a huge right-sided fronto-parietal angioma, who ultimately developed severe mental changes so that treatment in a mental hospital became necessary.

The history, the presence of a bruit and perhaps cutaneous vascular nævi would suggest the diagnosis of an arteriovenous malformation, and as with a neoplasm the electroencephalogram may indicate a focal abnormality. The essential investigation is angiography, only those lesions in the anterior temporal region occasionally escaping detection.

Mr. H. E. Hobbs: In the group of arteriovenous malformations which provide the material of this discussion, primary retinal vascular abnormalities appear to be rare unless the site of the intracranial lesion is so close to the eye that the vasculature of the globe is itself involved in the angiomatous process. Increased tortuosity of the retinal vessels has been described with intracranial angiomata remote from the orbit and in Northfield's (1940–41) case, an angiomatous formation close to the disc was seen. No such abnormalities were found in the series to which Dr. H. Dimsdale has referred, nor in those reported by Olivecrona and Riives (1948) or by Logue and Monckton (1954). Mackenzie (1953) and Dandy (1928) each include in their series a single case in which the retinal vessels were grossly distended and tortuous, the veins being virtually indistinguishable from the arteries, and in Paterson and McKissock's (1956) series 2 similar cases are included; but since these arose in conjunction with angiomatous lesions of the orbit or pituitary region, and the changes appear to have been of a secondary nature, I propose to refer to them separately in connexion with the orbital case which Dr. Dimsdale has already mentioned.

That primary vascular abnormalities are occasionally observed with intracranial lesions remote from the orbit, however, is demonstrated by Northfield's case (Northfield, 1940–41).

The main ophthalmological interest of the majority of these cases lies in the characteristic history of migraine, its association with other neurological abnormalities and the evidence of hemianopia when the progress of the lesion has led to a more or less permanent involvement of the visual fibres or cortex. Ipsilateral exophthalmos, which was regarded by Cushing and Bailey (1928) as a change resulting from progressive arterialization of the angioma, has not been seen in this series—possibly because it is a later manifestation of the condition.

With regard to the field changes: these usually follow and may closely resemble the early visual aura and are then commonly of the homonymous hemianopic type; but the defect, while succeeding a hemianopic aura, may occupy only a quadrant of the field, as was seen in a recent case (*vide infra*) which presented to me. It seems likely that these ensuing field defects are not all of them evidence of permanent ischæmic lesions of the visual neurones, but are in some cases the result of compression by an expanding lesion and potentially recoverable if this process is controlled, either spontaneously or by surgical methods. Such recovery is seen in some cases and is illustrated by that of a man (W. H. M.) whose right parietal angioma had, when he was first examined on 21.6.49, produced the incomplete lower left quadrantic hemianopia, shown in Fig. 1.

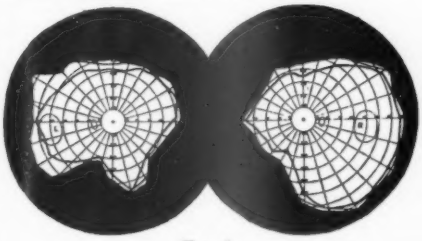

FIG. 1.

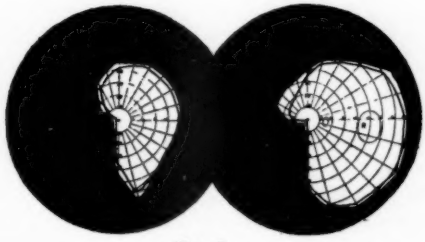

FIG. 2.

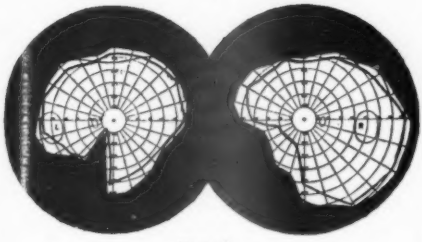

FIG. 3.

Within the next few weeks the defect increased to an almost complete hemianopia (Fig. 2). But following the ligation of the vessels supplying the tumour (Mr. Valentine Logue) a certain amount of recovery of the field was seen (Fig. 3). The importance of the characteristic history has already been emphasized; but as not infrequently happens with disorders of this type, it is the atypical case which appears in the ophthalmologist's consulting room, and the case which I have referred to above was of this type, for her history at first included no reference to migrainous headaches—these had ceased for some years when she presented complaining of bright spots of light in the right eye succeeded by a permanent ?-shaped black spot. She was moderately myopic, the vitreous of the eye in question showed an opacity corresponding to the black spot which she saw, and, after searching unsuccessfully for signs of retinal detachment, I accepted this as the cause of her symptoms with a provisional diagnosis of senile hyalitis. Within a week she had a severe left hemicrania with a hammering sensation in the skull, nausea and prostration followed by blindness on the right side and when I examined her a day or so later a right

inferior quadrantic hemianopia remained. Arteriograms subsequently revealed an angioma involving the left optic radiations. The case is of interest in this connexion, I believe, because of the diagnostic pitfalls which it presents, not only in the long silent interval between the attacks of migraine, but also in the quite unformed character of the spots of light which she saw at the onset of the attack.

Vascular abnormalities which directly affect the eye and orbit form a much smaller group, but one which is also of great interest to the ophthalmic surgeon. One such is included in the present series of cases, and is that of a man (J. H.) who for some years before his admission to Maida Vale Hospital had suffered from recurrent attacks of trigeminal neuralgia which were temporarily relieved by alcohol injections. For many years he had been aware of a cluster of tortuous venules on the temporal side of the sclera of his left eye and four months before I first examined him he had begun to have periodic attacks in which the eye became more congested, first in this region and later over the whole of the eye. The congestion gradually became more constant and proptosis developed whilst at the same time he began to notice a sound synchronous with the pulse, which he described as "squeaking" in his left ear. When I first saw him the proptosis of the left eye was some 7 mm. and chemosis was marked, vision in the eye was reduced to 6/18 and in the fundus gross distension of the retinal veins with œdema and hæmorrhages about the disc were apparent. A bruit, synchronous with the pulse, was audible maximally over the left temple. Arteriography shortly afterwards displayed an arteriovenous communication involving a group of the superior orbital vessels, and at operation a few days later (Mr. Valentine Logue) exposure of the orbital contents displayed a collection of greatly distended veins communicating with the ophthalmic artery. Ligation of these vessels effected a prompt cessation of the bruit and the proptosis very shortly subsided, with improvement in vision and restoration of the normal fundus appearance so that when I examined him a few weeks ago visual acuity was 6/9, the field full and the eye white, with the exception of the collection of varicose episcleral veins. The appearance of the fundus at this time was quite normal, without venous distension and with no suggestion of abnormal retinal vessels.

In this instance, therefore, although the proptosis and retinal changes arose from the presence of an arteriovenous malformation of the orbit they were evidently reversible and secondary to the arterialization of the retinal veins to which it gave rise. The mechanism is one which is common with such angiomata and examples of similar vascular lesions have been reported by Paterson and McKissock and by Mackenzie, whilst in Dandy's (1928) Case 12 a lesion in the pituitary region was responsible. It is probable, however, from the description which Cushing and Bailey give of their Cases 9, 11 and 14 in which arterialization of the retinal veins was seen with temporal and occipital angiomata, that similar changes may be seen with more remote lesions when circulatory changes become more widespread.

In such cases it is evident from the operative and arteriographic findings that the vascular abnormality has a more simple character than is the case with angiomata involving, say, the cerebral cortex where the collection of vessels may form a more or less circumscribed mass. Their essentially arteriovenous nature is the more obvious for this reason, and they tend clinically to bear some resemblance to carotico-cavernous fistulæ; but the insidious onset, absent or minimal pulsation of the eye and absence of trauma in the history are distinguishing features. In our case, however, the conspicuous collection of abnormal episcleral vessels provides a further indication of the presence of a primary vascular abnormality.

In contrast with such secondary retinal changes are those of the group in which the retina shows primary vascular abnormalities associated with retro-ocular angiomatous formations, the extent of which varies widely. It may be limited to the orbit and pituitary region or extend along the visual tracts as far as the mid-brain and even, as in one published instance, into the occipital lobe. The retinal picture varies in these cases and simple arteriovenous communications, enlarged and tortuous vessels which in some cases are abnormally numerous, have been described. Circumscribed angiomata and secondary retinal changes are sometimes seen; but retinal detachment has not been reported although Northfield refers to the occurrence of glaucoma in two instances. Optic atrophy has been noted several times and papillœdema is seen as a secondary change with raised intracranial pressure.

An angiomatous appearance of the retina was recorded in a case (No. 3) described by Brock and Dyke (1932). The eye was blind and proptosed and the neurological abnormalities present arose from the angioma which was seen at post-mortem to extend from the eye along the optic nerve and tract to the mid-brain and thence into the cerebellum. The case is of especial ophthalmological interest since the histological appearances of the eye were subsequently reported on by Krug and Samuels (1932) who verified the changes as those of a venous angioma. Retinal changes of this type were seen also by Olivecrona and Riives (1948) in a patient with a lesion extending to the mid-brain. In Yates and Paine's (1930) case in which the ocular signs consisted of homonymous hemianopia and slight proptosis, the retina showed only slight dilatation of the vessels; but with a collection of aneurysms at the periphery. Professor Bonnet of Lyons (Bonnet *et al.*, 1937) also reported a case in

which hemiplegia, ocular palsies and exophthalmos with an audible bruit over the affected eye occurred with the angiomatous appearance of the retina.

These extensive angiomatous formations were the subject of an interesting review by Wyburn-Mason (1943) and his paper contains a collection of fundus pictures drawn from many sources which demonstrates the considerable variation in the vascular anomalies met with in this connexion. His own Case 7 is of especial interest since the sole retinal abnormality which accompanied the intracranial lesion was a single arteriovenous aneurysm.

Optic atrophy has been apparent in association with other defects in several of the published cases; but that it may present as the sole neurological sign is shown by the case reported in 1952 by Band from the United States. Here the angioma demonstrated by angiography and operation surrounded the chiasma and one optic nerve. The case may be correlated with that of the man (W. J.) with cutaneous angiomata, postural proptosis and a spastic limb (shown at the Meeting). The angioma in this instance has been shown by angiography to extend from the orbit upward toward the basal ganglia and, although the retinal vascular changes are not marked, the suggestion of atrophy at the disc is confirmed by the visual field defect (Fig. 4).

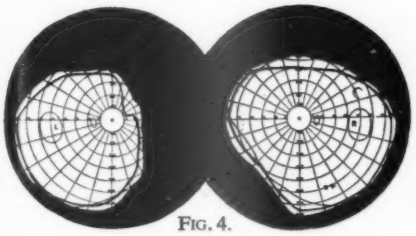

FIG. 4.

The possibility of such an explanation of optic atrophy is clearly, therefore, one to be borne in mind. How far arteriography can be expected to assist in displaying the nature and extent of the lesion in such cases is a matter which Dr. David Sutton will discuss.

Dr. David Sutton (St. Mary's Hospital, London, and Maida Vale Hospital for Nervous Diseases): *Radiology of Cerebral Angiomas* [*Summary*][1]

Cerebral arteriography has proved the most important means of investigation in the diagnosis of cerebral angiomas and is largely responsible for the elucidation of the clinical pictures presented by them. These lesions were considered rare until quite recently. Cushing's monograph (Cushing and Bailey, 1928) based on a vast experience of neurosurgery, was able to cite only 15 cases. In recent papers Mackenzie (1953) was able to quote 50 cases, and Paterson and McKissock (1956) quote 110 cases. The writer has personally performed arteriograms on over 100 cases in the last ten years. At Maida Vale Hospital 60 cases of angiomatous malformation have been diagnosed by arteriography in the last six years. This is entirely due to the routine use of cerebral arteriography. However, plain X-rays may also be most helpful.

Abnormalities seen on plain X-rays.—These are seen in a relatively small proportion of cases but can be diagnostic. They consist of: (1) Abnormal vascular channels in the skull vault, in particular hypertrophied and tortuous meningeal vascular channels. These must be differentiated from the similar changes seen sometimes with meningiomas. (2) Calcification. This has been recorded in 10% to 24% of cases in different series. In my own series it was present in 16 cases or 14%. The calcification is often pathognomonic, and in typical cases consists of scattered linear flecks of calcium in the area of the angioma, of a type quite unlike that seen with neoplasms and other intracranial lesions. Sometimes associated annular shadows are seen similar to those described with intracranial aneurysms, These lie in the walls of aneurysmal dilatations in the malformations.

Angiography.—The investigations required depend both on the site and the size of the lesion. In many cases bilateral carotid arteriograms will be required; in others vertebral arteriography will be necessary, sometimes in combination with unilateral or even bilateral carotid arteriography to reveal the total extent of a large angioma and all its vessels of supply

[1]This paper with illustrations is being reproduced in full in *J. Fac. Radiol.*

and drainage. Angiomatous malformations have been called "parasites" or "sponges" in the way they suck blood from all sources of supply. This can be well demonstrated by the arteriograms. The vessels leading to the angioma are hypertrophied, vessels not supplying it are often hypoplastic or fail to fill. Frequently arteriography of the contralateral carotid artery shows blood being sucked across the mid-line to feed the angioma.

Most angiomas show abnormal large veins draining the lesion. These can reach gigantic size. Arteriography shows that they opacify early because of the arteriovenous shunt. Many of the lesions we have considered in this discussion are supplied by the posterior cerebral artery, and it is common for these to be filled equally by the carotid and vertebral arteries. Smaller angiomas occur which can only be demonstrated from one major feeding artery. With tiny and less typical angiomas visualization of a dilated vein in the arterial phase of the arteriogram may be the feature most suggestive of angioma. Such lesions frequently manifest by subarachnoid hæmorrhage or by rupture into the brain with the formation of a cerebral hæmatoma. In this case clotting may occur in the lesion and the tiny angioma may become extremely difficult to identify at arteriography.

Pneumography.—Usually normal appearances are seen, but abnormalities may be seen in three types of case:

(1) Giant angiomatous malformations. These may show the same types of deformity of the ventricular system as those presented by any intracerebral expanding lesion.

(2) Smaller angiomas adjacent to and protruding into the ventricles.

(3) Angiomas complicated by intracerebral hæmorrhage, in which the hæmatoma acts as an intracerebral expanding lesion to deform the ventricular system.

The clinical aspects which concern the ophthalmologist have been described by my colleagues. The most important mode of presentation to the ophthalmologist appears to be *periodic migrainous headache with a visual aura* of the type described, i.e. constant and homonymous in nature. Such symptoms were present in 10 of my cases. *Homonymous field defects* were present in 6 cases. In this group the angioma lay in the occipital, parieto-occipital or temporo-occipital regions. Field defects were sometimes seen with large temporal or para-sellar angiomas. *Papillœdema* was rare but was present in a few cases, usually with excessively large angiomas or following intracerebral hæmorrhage.

Pulsating exophthalmos occurred in one case. *Defects of ocular movement of central type* were seen in 4 or 5 cases, though they were not the presenting or most prominent sign. They were most common with angiomas in the region of the mid-brain.

PATERSON, J. H., and MCKISSOCK, W. (1956) *Brain*, **79**, 233.

The President said that in the course of his research, Mr. Hobbs had come across the notes of a young man whom he, the President, had seen recently. He had had a convergent squint in the left eye since the age of 21 months, and the vision from the eye had always been "very weak". Since the age of 14 he had had visual disturbance, and visible retinal changes in the right eye. These had recently extended. On examination the squinting eye showed so-called primary optic atrophy, with no evidence of previous œdema of the nerve head. The right fundus showed in the upper nasal region a large cystic detachment of the retina, with diffuse tortuosity of all blood vessels in that quadrant. There were smaller areas of detachment in the temporal and upper temporal regions, which in a few months became confluent with the nasal "cyst". The vascular picture in the one eye, and the unexplained optic atrophy in the other, suggested that the next move might be to get Dr. Sutton to undertake arteriography, as straight X-ray of the skull had revealed no abnormalities, and the retinal condition was quite atypical of hæmangioblastoma.

Mr. E. F. King referred to a case of his own, a man of middle age who had been attending his clinic for a number of years. In the upright position both eyes of this patient were enophthalmic, but when he leant forward, or when pressure was applied to the vessels at the root of the neck, the eyes temporarily became prominent. Another interesting feature was that this patient had advanced bilateral simple glaucoma and was, in fact, now blind. He had always assumed that there must be some congenital malformation in the drainage channels of the eye itself, and he wondered if such an association with orbital angiomata had been noted by others.

Another case was that of a child. Last year, when she was a few months old, she developed proptosis. A retro-ocular tumour had been diagnosed and radiation to the orbit initiated. A further examination showed, in addition to the proptosis, a cluster of dilated veins in the temporal region on the same side as the affected eye. It seemed probable that the child had an orbital angioma and that the proptosis, which appeared rapidly, was due to a hæmorrhage from it. All treatment was stopped and the proptosis subsided completely within a few months.

The Radiological Diagnosis of Pulmonary Embolism

By SHIRLEY ROBERTS, M.B., B.S., M.C.R.A.

Radiodiagnostic Department, Royal Infirmary, Bristol

THE clinical picture presented by a typical case of pulmonary embolism is well defined and characteristic. By contrast, the radiological diagnosis is often uncertain, and the clinician, as a result, may regard chest radiography in suspected pulmonary embolism as either unnecessary or valueless. Further observation tends to show, however, that this is not a true representation of either the clinical or radiological aspects of pulmonary embolism.

PATHOLOGICAL FINDINGS

The inconsistency of both the clinical and radiological features is a reflection of the variety of the pathological changes which may occur and these are related to the anatomy of the pulmonary vasculature. The branches of the pulmonary artery correspond in their distribution to the subdivisions of the bronchial tree, there being no significant anastomoses between the branches to neighbouring segments or subsegments. However, there are important pre-capillary anastomoses between the bronchial and pulmonary arteries. Probably they are normally contracted, but in a number of pathological states become patent.

Hence, although occlusion of a branch of the pulmonary artery produces potential ischæmia of the whole of the segment or subsegment it supplies, the actual extent and severity of the change produced depends largely on the adequacy of the broncho-pulmonary anastomoses.

There is thus a range of possible parenchymal changes:

(*a*) Minimal ischæmia, without significant effect on the parenchyma; (*b*) incomplete infarction, with early return to a normal appearance; (*c*) production of a hæmorrhagic infarct, with ultimate replacement fibrosis.

Infarction may be delayed in onset, due to spreading thrombosis or repeated embolic episodes.

RADIOLOGICAL APPEARANCES

These reflect the complex nature and course of the pathological changes. Four elements compose the radiological picture; (*a*) Changes in the pulmonary parenchyma. (*b*) A pleural reaction. (*c*) Alterations in the diaphragmatic contours. (*d*) Changes in the vascular pattern.

(*a*) *The parenchymal lesion.*—(i) *Site:* A whole lung, lobe or segment may be involved, or the lesion may be subsegmental. However, it always involves a pleural surface and is often at the junction of two pleural surfaces, e.g. costophrenic angle. This peripheral situation is probably due to the fact that ischæmia is maximal in the most distal portion of the field supplied by the occluded vessel. (An analogous phenomenon occurs when some peripheral arteries are occluded; obstruction of the popliteal artery frequently results in gangrene of the toes only.) Approximately 75% of infarcts occur in the lower lobes and they are slightly more common on the right side than on the left. They are frequently multiple, but an upper lobe is rarely involved unless there are also lower lobe lesions.

(ii) *Shape:* The infarct shadow has not, as was once thought, a typical shape. Since it corresponds to a segment, or a peripheral portion of a segment, its shape depends on the projection in which it is viewed. Thus, while it may be wedge-shaped, with its apex pointing towards the hilum, it has more commonly a rounded or "humped" cardiac border with its longest edge applied to a pleural surface (Fig. 1A, B). An infarct occurring in a costophrenic angle has a characteristically convex superomedial margin which enables it to be distinguished from a small effusion (Fig. 2).

(iii) *Density:* The density of the opacity depends on the stage of the lesion. In the early

phase, when there is passive congestion of the alveoli, while the alveolar ducts and atria are still aerated, the parenchymal lesion is represented by a poorly defined area of vague clouding. In cases of incomplete infarction this may be the maximal abnormality observed, serial films showing complete resolution of the opacity within a few days. When the lesion progresses to complete alveolar necrosis, the opacity remains homogeneous but becomes considerably denser and more clearly defined.

(iv) *Time of appearance and duration:* The interval between the onset of clinical signs and symptoms of embolism and the appearance of a parenchymal density in serial films is very variable. Not uncommonly, films taken within the first twenty-four hours fail to show any abnormality, but on the second or third day a large infarct shadow may be apparent (Fig. 3).

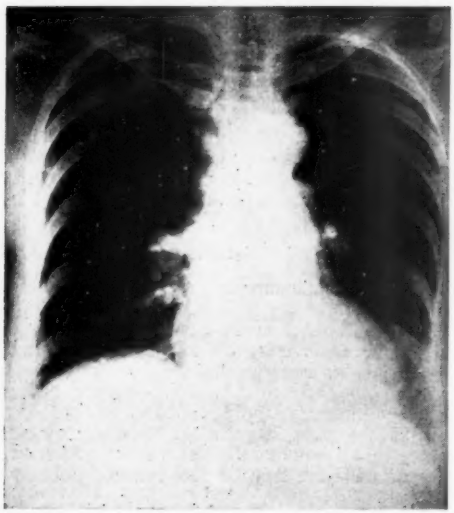

FIG. 1A.—A vague left lower zone opacity is apparent in the P.A. view.

FIG. 1B.—In the left anterior oblique view it is seen to consist of a well-defined parenchymal density with a small pleural effusion.

FIG. 2.—A costophrenic angle infarct with characteristically rounded supero-medial margin.

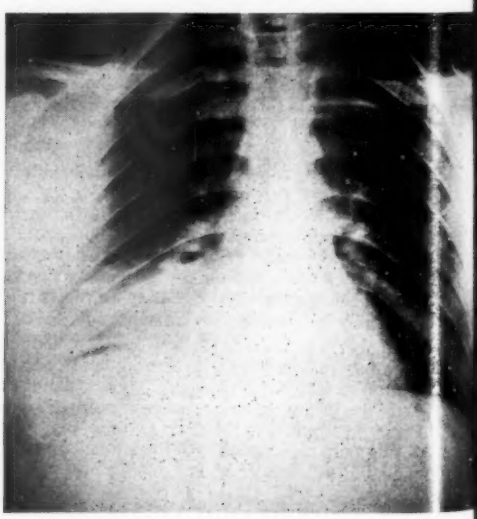

FIG. 3.—Post-operative infarction. Twenty-four hours after the onset of right basal infarction. A film at five hours had shown no abnormality.

On the other hand, a lesion detectable early in the course of the illness may, if due to incomplete infarction, resolve rapidly, so that there may be no radiological evidence of its occurrence a few days later. Hence, repeated examinations at short intervals may be necessary to demonstrate the infarct. Such repeated examinations may also reveal extension of the lesion due to spreading thrombosis.

(v) *Resolution and healing.*—The rate of the healing process in hæmorrhagic infarction depends on the size of the lesion and on the efficiency of the pulmonary circulation. As the mass of necrotic tissue is absorbed and replaced by connective tissue, the lesion decreases in size. Serial films thus show, usually from the second week onwards, progressive shrinkage of the infarct density. If the lesion has been extensive, radiological evidence of loss of pulmonary substance—displacement of interlobar fissures—will also appear at this stage, although not evident earlier.

Most commonly, a small fibrous scar, not detectable radiologically, represents the stage of complete healing. However, larger infarcts may result in a permanent network of irregular linear shadows due to bands of scar tissue. There is often localized pleural thickening overlying these lesions (Fig. 4).

FIG. 4.—Linear scars remaining after a left lower infarct which occurred seven months previously.

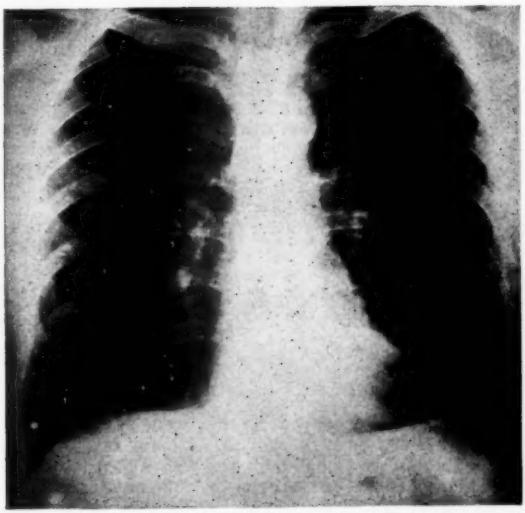

FIG. 5.—Transient irregularity of the left diaphragmatic contour, the only radiological sign observed in this case of left basal pulmonary embolism.

Occasionally an infarct is too large to permit of complete fibrous replacement and the hæmorrhagic centre persists indefinitely. The associated radiological abnormality—a parenchymal shadow devoid of characteristic features—may present diagnositic difficulties if encountered for the first time long after the embolic episode.

(*b*) *The pleural reaction.*—A pleural reaction, detectable radiologically, is present in less than half the cases. Moberg (1948) investigated the incidence of effusion within the first three days of illness in a series of cases of pulmonary embolism, as compared with bronchopneumonia of the same duration. He found that, in 21 of his 46 cases (i.e. 45%) of embolism, an effusion was the dominant radiological feature, overshadowing the parenchysmal density. In only 2 of the 23 cases (9%) of bronchopneumonia was an effusion, rather than a parenchymal density, the major radiological abnormality.

The extent of the effusion in cases of embolism varies from a thin layer, detectable perhaps in only one projection, to massive collections obscuring most of the underlying lung. Small effusions are sometimes detectable in P.A. or A.P. films taken with the patient lying on the affected side and using the horizontal beam, but the standard oblique projections are also helpful (Fig. 1). Localized pleural thickening may remain to indicate the site of an old infarct.

(*c*) *Changes in the diaphragmatic contours.*—Short (1951) found elevation of the diaphragm in 35% of cases. Occasionally it is the only radiological abnormality in cases where the

clinical diagnosis is definite (Fig. 5). Transient elevation of the diaphragm on the side of the lesion may be noticed in the first few days of the illness. In other cases it appears, and persists, when healing of the lesion is associated with a decrease in lung volume.

(*d*) *Changes in the vascular pattern.*—A different sign, of considerable radiological interest, is that described by Westermark (1938). This consists of the appearance of an area of reduced vascularity, apparently due to spasm of the vessels distal to the occlusion. The only vascular markings visible within the ischæmic zone are those of the bronchial vessels. This appearance may persist for a number of hours and then be replaced by a return of the normal vascular pattern, or by the appearance of an infarct shadow. Enlargement of the area of ischæmia indicates spreading thrombosis and is of serious prognostic significance.

Conclusion

There is no commonly found radiological appearance which is completely characteristic of pulmonary embolism. However, there is a group of signs which, in their relation to each other and to the clinical picture, constitute a pattern which can be recognized as being due to embolism rather than to the various conditions resembling it.

Many cases of pulmonary embolism cannot be diagnosed on clinical evidence alone. Even in very ill patients, radiography of the chest with portable apparatus causes minimal disturbance and there is ample justification for using this diagnostic aid.

Acknowledgments

The author is indebted to Dr. J. H. Middlemiss for his advice and encouragement and to Dr. F. G. M. Ross and Dr. I. R. S. Gordon for their helpful criticism.

Radiological Manifestations of Ectopic Salivary Adenomas showing the Cylindroma Pattern

By Max J. Ryan, D.M.R.D.

Senior Registrar, Manchester Royal Infirmary and Christie Hospital and Holt Radium Institute

This short paper describes some of the interesting features of a rare tumour which is found in and around the mouth. Locally it grows slowly but travels extensively, with a tendency, in some cases, to invade the base of the skull. Its most striking characteristic is the production of pulmonary metastases which show little increase in size or number over a long interval of time.

The benign mixed salivary adenoma is one of the commonest adenomatous tumours found in the anterior foregut. It usually arises in one of the large serous salivary glands—namely the parotid or submandibular—and its course is usually benign. Rarely, however, adenomatous tumours are discovered outside the large salivary glands, for example, in the hard palate, the soft palate, the tongue, the antra and the post-nasal space. Rightly or wrongly, these tumours are described as arising in ectopic sites.

In the Christie Hospital it has been found that many of these tumours arising in an ectopic site have recurred after treatment of what was originally considered to be a benign mixed salivary adenoma. Some of these tumours even gave rise to regional and distant metastases.

As a result, it was decided to review all the histological material of the adenomas arising in ectopic sites between the years 1937 and 1952. A total of 82 was found, which Russell (1955) has classified as follows:

Cylindromas, 46; Mixed adenomas, 29; Other adenomas, 7.

The Cylindroma

Russell has described the cylindroma as a specific variety of the mixed salivary adenoma. It is essentially an adenoid structure which appears to arise from the mucous glands, which are most common in the buccal cavity and upper respiratory tract. The cylindroma has quite a distinct pattern, a special stain showing successive zones or cylinders of cells, which gave rise to the term cylindroma. It is incompletely encapsulated and grows slowly. Initially bone erosion is caused by extrinsic pressure rather than malignant invasion. Harrison (1956) in his Hunterian lecture has reported on the clinical behaviour, treatment and prognosis in this same series of cases.

The material which I have studied is this group of 46 cases reported by Harrison (1956) and Russell (1955), and some 9 others which have since been added, making a total of 55 cases in all. Of these 55 cases, radiological investigations were carried out in 32, and X-ray changes were found in 24. All the cases were not submitted to X-ray examination—for example, when the primary was situated in the tongue, floor of mouth and fauces. There were 6 cases of metastases to lung and 2 to bone.

Radiological manifestations of the cylindroma have been found in the nasopharynx, the antrum, the hard palate and the orbit. The following is the incidence in each site:

Nasopharynx, 8; Antrum, 6; Hard palate, 8; Orbit, 2.

My first case shows how the cylindroma may behave in the post-nasal space.

A man aged 42 presented with a history of recurrent attacks of pain on the left side of the hard palate for *eight* years. On examination he was found to have a lesion of the left trigeminal nerve.

X-ray examination of the skull showed enlargement of the left foramen ovale.

On exploration of the left middle cranial fossa a "berry-like" tumour was seen protruding from the left foramen ovale and foramen spinosum. The tumour was completely extradural and was infiltrating the left trigeminal nerve. On histological examination it was found to be a cylindroma.

The involvement of the trigeminal nerve appears to be a characteristic feature of many tumours found in this region as described by Sir Geoffrey Jefferson in his Bowman Lecture of 1953.

Further X-ray investigation after the operation and review of the previous films revealed the following features. On the basal view (Fig. 1), in addition to the enlarged left foramen ovale, there was opacity of the left sphenoidal sinus, left nasal cavity and possibly the left antrum.

A lateral view of the neck disclosed definite evidence of a nasopharyngeal tumour (Fig. 2).

FIG. 1.—Basal view of skull showing enlargement of the left foramen ovale and opacity of the left sphenoidal sinus and left nasal fossa.

FIG. 2.—Tumour in post-nasal space.

The occipito-mental view showed opacity of the left antrum.

There was also loss of translucency in the ethmoidal air cells and enlargement of the left sphenoidal fissure.

On tomography of the antra and ethmoidal sinuses the tumour was found to have eroded the floor and the medial wall of the left orbit. The tomograms also demonstrated destruction of the turbinates of the left nasal cavity and thinning of the medial wall of the left antrum.

On follow-up examination fifteen months later there was involvement of the right antrum in addition to the left, but there was no further intracranial extension. It is remarkable that in spite of all these changes the patient continues to enjoy moderately good health.

This case illustrates that when a cylindroma is proved or suspected, an extensive radiological examination is essential to reveal all the extensions of the tumour.

The antrum was the site of origin in 6 cases, all of which showed radiological changes.

The next case illustrates the progress of a cylindroma of the antrum over five years.

Radiologically this man of 41 presented with a tumour of the right antrum, which was destroying the floor of the orbit and invading the nasal fossa (Fig. 3A). It will be seen that there was no evidence of involvement of the left antrum. He was treated by radical excision of the right maxilla and insertion of a radium tube.

Three years later he complained of a bulging right eye. X-ray examination revealed the presence of extensive and widespread tumour recurrence (Fig. 3B). There was tumour in the right nasal cavity and extension across the nose into the left antrum. The well-defined opacity in the right infra-orbital region was due to the operative defect. Recurrence was also found in the right ethmoidal region with thinning of the floor of the anterior fossa. Subsequent operation confirmed the X-ray findings. Tumour recurrence was present in all areas.

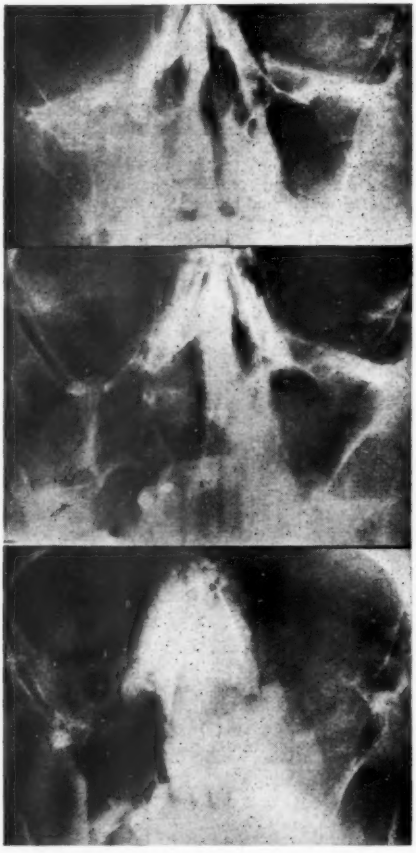

FIG. 3A.—Antral tumour destroying the floor of the right orbit and invading the nasal fossa.

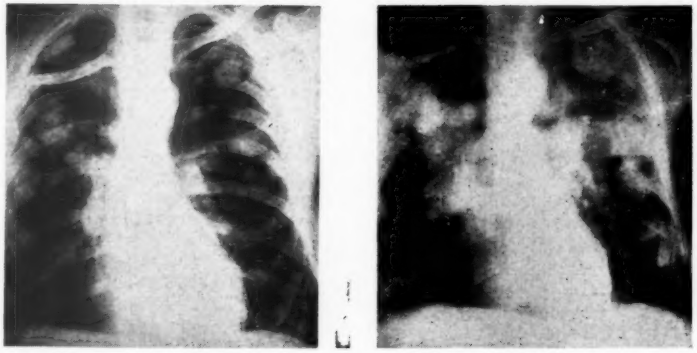
FIG. 3B.—Three years later—tumour recurrency in right nasal cavity with extension across the nose into the left antrum.

FIG. 3C.—Two years later—left maxillary sinus completely filled with tumour which has destroyed the floor of the left orbit, and the medial wall of the antrum.

After another two years he began to complain of protrusion of the *left* eye. Radiological examination showed that the left maxillary sinus was now fully occupied by the tumour, which had completely destroyed the floor of the orbit and the medial wall of the antrum (Fig. 3C). The nasal cavities and ethmoidal sinuses were packed with the growth, and there was erosion of the greater and lesser wings of both sphenoid bones.

Despite this long course and the presence of extensive destruction, the general condition of the patient is reasonably good.



The hard palate is the commonest site for the cylindroma to be found clinically, but only a small number show X-ray changes. Radiologically the hard palate tumour often simulates a malignant antrum. Sometimes in an advanced case it is impossible to differentiate between the two.

The next case is an example of a cylindroma which first presented as an orbital tumour.

A man of 47 gave a two-year history of pain behind the left eye, and more recently proptosis and diplopia. Radiological examination of the skull showed some loss of definition of the margins of the greater and lesser wings of the left sphenoid (Fig. 4).

FIG. 4.—Erosion of the greater and lesser wings of the left sphenoid bone.

A B

FIG. 5.—Multiple round cannon-ball metastases—six-year interval between films A and B.

At operation a tumour was found behind the left orbit and in the left pterygoid region, which was invading the temporal fossa.

METASTASES

A surprising feature of the cylindroma is its tendency to produce pulmonary metastases. Here we have a relatively innocent tumour, which invades locally but grows very slowly over the years, and yet we have *six* cases of metastases in the lungs. The amazing characteristic of these cylindroma metastases is that they grow very slowly, like the primary, and the patient is free from symptoms.

Fig. 5A was a routine chest X-ray taken in 1950, eight years after treatment of a cylindroma of the antrum. The patient, a male nurse, had no reason whatsoever to suspect that he had any chest disease. The prognosis given at that time was, of course, extremely poor—at the most six to nine months. Since then chest X-rays have been taken at regular intervals and Fig. 5B was taken three weeks ago. It is remarkable that there has only been a moderate increase in the size and number of the metastases over six years and even stranger is the fact that the patient is well and has had no recurrence of his primary.

CONCLUSION

The cylindroma is notoriously difficult to diagnose, both clinically and radiologically. The changes due to the primary tumour can be produced by many other lesions. The diagnosis is essentially a pathological one, and may give rise to considerable difficulty.

When the cylindroma has been diagnosed, radiology can make a definite contribution by disclosing all the extensions of the tumour which may not be suspected clinically.

A chest X-ray must not be omitted, for the finding of round well-defined metastases in the lungs, which show very little change over a long interval, enables the radiologist to make a fairly confident diagnosis.

ACKNOWLEDGMENTS

I wish to express my sincere thanks to Dr. E. Duff Gray and Dr. J. Blair Hartley for their constant encouragement and advice, to Mr. Kenneth Harrison, Mr. R. T. Johnson, Dr. Ralston Paterson, Mr. W. F. Nicholson, and Dr. Helen Russell for permission to publish cases and to Dr. R. G. W. Ollerenshaw and his staff of The Department of Medical Illustration for the excellent prints.

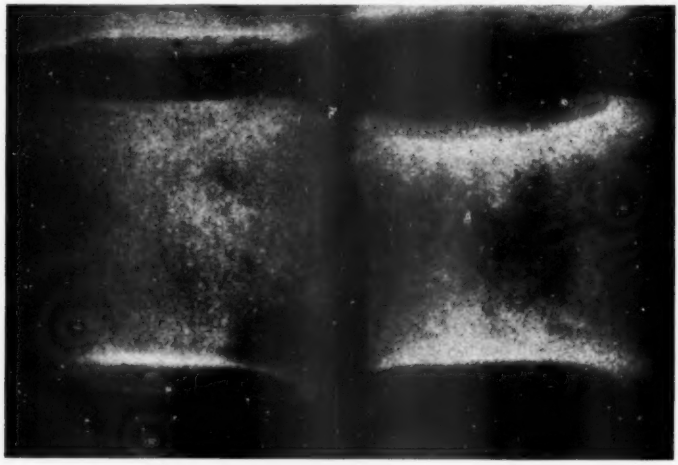
Bone Changes in Myelosclerosis

By F. MULCAHY, M.B., B.Ch., D.M.R.D.



Department of Diagnostic Radiology, Manchester Royal Infirmary

MYELOSCLEROSIS is a rare disease of unknown ætiology occurring in later life and characterized by leuco-erythroblastic anæmia, progressive splenomegaly, obliteration of the normal bone-marrow by fibrous tissue and frequently by cancellous bone. Many cases appear to have been described under various other titles such as Myelofibrosis, Osteosclerosis, Osteomyelo-reticulosis, Aleukæmic Ossifying Myelosis and Megakaryocytic Leukæmia. Some writers refer to primary and secondary myelosclerosis. I shall describe the primary or idiopathic form. The secondary type refers to the sclerosis which occurs in bone as a result of other conditions, such as Generalized Osteoblastic Carcinoma; Osteitis Deformans; Hodgkin's Disease; Syphilis and Post-radiation Sclerosis.

The present study is based on a detailed investigation of 28 cases of the disease by Leonard *et al.*, in the Manchester Royal Infirmary. I propose to summarize the findings and correlate the radiological appearances with these.

The sex distribution of cases was equal in the series. The onset of the disease was insidious and was frequently unnoticed until it was well established. The majority of patients were over 45 years and presented with symptoms of:

I. Anæmia, such as dyspnœa, tiredness and angina pectoris.
II. Splenomegaly, such as a heavy feeling in the abdomen or distension after meals.
III. Bone involvement, such as deep-seated pain in the shoulder or hip-joint regions and occasionally over the shafts of long bones.

A B

FIG. 1.—A, Normal vertebral body. B, Myelosclerotic vertebral body showing alteration in trabecular pattern, with increased density close to the cartilaginous plates.

It is interesting to note that the patients who complained of bone pain showed well-marked radiological bone changes.

[Dr. Mulcahy then reviewed the changes seen in the peripheral blood and bone-marrow and stated that sternal marrow aspiration was impossible in 50% of cases. He showed several photomicrographs of bone-marrow taken from biopsy specimens and pointed out that the quantity of new bone deposited upon the trabeculæ varied considerably from case to case, observing that the degree of change noted on the bone films was related to this.]

I have examined the skeletal survey films of 19 cases where the diagnosis was confirmed by bone biopsy. In 10 there were no detectable abnormalities. 9 showed X-ray changes of varying degrees. Of these, 4 were abnormal on casual inspection. The remaining 5 showed definite but less well-marked changes.

The bones most frequently involved are those of the central skeleton. The changes are less conspicuous towards the periphery. The bones distal to the elbow-joint are normal in all cases and I have only seen bone involvement below the knee-joint once.[1] No skull changes are present in any of the cases. These findings agree with those of other observers.

Some difficulty may be experienced in detecting the earlier changes, but Brailsford (1953) pointed out that the alterations are easier to appreciate if the films are examined with those

A B

FIG. 2.—A, Myelosclerotic bone showing granular density and loss of trabecular pattern. B, Normal ischium and pubis.

of similar areas in normal cases. I have found this valuable, but there is such variation in the structure and architecture of normal bones that I have used several control films for each site because of difference in sex, age and bone size.

In some cases the earliest detectable changes consist of a widening and increased prominence of trabeculation against a background of slightly increased density. Other cases show patchy ill-defined areas of sclerosis, an appearance which may occasionally be mistaken for metastatic deposits. Others show larger areas of generalized amorphous or granular increase in density in which the spongiosa architecture cannot be identified. This appearance is usually found in the ischium pubis and ribs, where trabeculation is normally fine.

In more advanced cases, the ordered well-defined medullary pattern is replaced by coarse irregular trabeculæ which have ill-defined edges. The inner margin of the cortex is sometimes uneven and poorly differentiated from the medulla.

Vaughan and Harrison (1939) have described, in addition to other changes, a marked decreased density of cortical bone together with subperiosteal new bone formation. I believe their cases were more advanced than those which I have reviewed. The longest observed

[1] ADDENDUM.—Since this paper was delivered I have seen two advanced cases of myelosclerosis in which the bone changes extended as far as the wrist and ankle joints. In addition, one of them showed a small periosteal reaction at the lower end of the femur.

case in the present series was first seen four years ago and the patient is still alive. I have not noted any periosteal new bone formation or accentuation of muscular insertion sites.

The following are some examples of the abnormalities found. The pelvic bones of a man of 65 years, who complained of weakness, dypsnœa and anorexia for two years show a generalized increase in density. Patchy areas of sclerosis are present in both ilia and in the upper femora, where trabeculation is coarse. Closer examination of the ischium and pubis, together with a normal control, reveals an amorphous increase in density with obliteration of the trabecular pattern. A generalized density affects all the ribs, the individual trabeculæ being ill-defined. In the lower aspects of the scapulæ areas of sclerosis are present. The dorsal spine, in addition to some generalized increase in density, shows small central sclerotic areas. Patches of sclerosis and trabecular alteration are present in the upper humeri.

A woman of 61 years complained of symptoms of anæmia and discomfort, due to splenic enlargement, for two years prior to examination. In the pelvic bones, widening and coarsening of trabeculation are present and the enlarged splenic shadow is visible on the film. When compared with a normal control the trabecular alteration is more striking, especially in the femoral heads.

FIG. 3.—Femoral neck showing increased prominence of the weight-bearing trabeculæ.

FIG. 4. — Upper humerus. Note trabecular alteration, hazy sclerosis and ill-defined areas of porosis.

The next patient, a woman of 48 years complained of symptoms, due to anæmia and splenomegaly, for only two months before her X-ray examination. The bone texture of the vertebral bodies is obviously abnormal. Trabeculation is coarse and ill-defined, but the increased density is a little more marked close to the cartilaginous plates, giving a "sandwich effect". Fig. 1B shows this appearance in one of the vertebral bodies, together with a normal control (Fig. 1A). Schinz *et al.*, (1951) referred to this type of change in myelosclerosis. It is, however, a more marked feature of osteopetrosis and I have seen it in a case of healing osteomalacia, but in these diseases other distinguishing features are present.

A woman was admitted for treatment of pyelitis. An enlarged spleen was noted and blood examination suggested the possibility of myeloid leukæmia. The sternum was so sclerosed that marrow could not be aspirated, so myelosclerosis was considered probable. A bone biopsy confirmed this diagnosis and the specimen showed marked increase in the size and irregularity of trabeculation. Skeletal survey films show generalized increased density of the pelvic bones and there are ill-defined sclerotic areas present in the right upper femur. The granularity and loss of trabecular pattern is noted in the ischium and pubis (Fig. 2A) when compared with a normal control of the same region (Fig. 2B). In the femoral neck (Fig.)

there is increased prominence of the weight-bearing trabeculæ. The upper humerus (Fig. 4), also shows hazy sclerosis with disordered trabeculation and ill-defined areas of porosis are also present. The appearance here could possibly be confused with metastatic deposits if complete skeletal films were not examined.

The next case also shows changes mimicking secondary deposits. Small dense areas are present in the centres of the vertebral bodies (Fig. 5). Similar areas of increased density are also present in the lower humerus (Fig. 6). The remaining skeletal films of this case show changes more indicative of myelosclerosis than metastases.

Splenomegaly is found in all cases, but in considering the differential diagnosis we must remember that splenic enlargement is also associated with bone changes in many other conditions.

In myelosclerosis the internal architecture of the bones may be altered in varying degrees so that radiological changes may be absent, slight or marked depending on the amount of new bone deposition upon the trabeculæ. The symptoms of the disease appear to depend on the extent of marrow fibrosis and the effectiveness of extra-medullary hæmatopoietic activity. Full skeletal survey films to include the skull should be done in all cases where sternal marrow aspiration proves impossible and whenever an enlarged spleen, together with

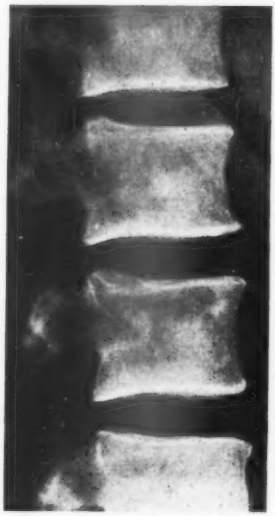


FIG. 5.—Lumbar vertebræ showing rounded dense areas in the centres of the vertebral bodies.

FIG. 6.—Lower humerus containing ill-defined areas of sclerosis.

any alteration in the bone texture, is noted in a patient past middle age. Control films should be used if necessary. When changes such as I have described are found, the case is probably one of myelosclerosis.

ACKNOWLEDGMENTS

I wish to thank Dr. E. Duff Gray, Director of Diagnostic Radiology, Manchester Royal Infirmary, for his help and encouragement, also Dr. B. J. Leonard, Dr. M. C. G. Israëls and Dr. J. F. Wilkinson of the Department of Hæmatology, for their valuable assistance and for allowing me to study their cases. I am grateful to Dr. R. G. W. Ollerenshaw and The Department of Medical Illustration for the reproduction of the radiographs, and to the staff of the Department of Pathology for the photomicrographs.

Electroencephalography in Relation to Anæsthesia [*Abridged*]

REGISTRARS' PRIZE ESSAY

By SHEILA M. WILSON, M.B., F.F.A.R.C.S., D.A.

THE electroencephalogram is the record obtained using indirect leads of the changes in electrical potential taking place in the grey matter of the cerebral cortex, the electrodes being placed at two points on the scalp.

PHYSIOLOGICAL BASIS OF THE ELECTROENCEPHALOGRAM

At rest the electrical discharge from the cortical cells results in a wave pattern with a frequency of 9–10 cycles/second and amplitude of 50 microvolts (Fig. 1A). This type of record is produced by a whole mass of cells discharging synchronously at approximately the same rate. If the electrical activity were produced by smaller groups of cells discharging asynchronously and at different rates, the resulting record would consist of innumerable irregular excursions rather than a recurring pattern. This, in fact, occurs in the recordings made during mental activity, especially visual activity where the large regular alpha waves are replaced by small irregular oscillations (Fig. 1B).

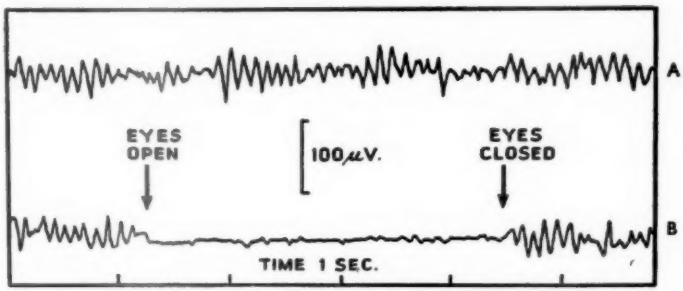

FIG. 1.—(Reproduced from Wright, S. (1952) by kind permission.)

Experimentally it has been shown that the resting discharge is due to the existence of a closed circuit between cortex and thalamus—impulses from the cortical cells reach the thalamus, cause an electrical discharge from the thalamus, which in turn stimulates the cortex again. Each time the circuit is traversed the cortical discharge produces the wave form recorded in the electroencephalogram.

In certain states of anæsthesia the cortical potential waves occur in groups separated by intervals of inactivity. Appropriate stimulation of the medial thalamus during a silent interval can set up typical runs of alpha waves in the cortex. This response occurs in areas of cortex which are connected only by thalamo-cortical fibres, so that the pathway between thalamus or cortex is a direct one.

These findings suggest that at the level of anæsthesia associated with periods of suppression of cortical activity there must be a depression at some point in the cortico-thalamic circuit. As the cortex remains capable of responding to stimuli, this depression must occur at thalamic level or below; that is, either the thalamus is not capable of responding to its normal stimulus or that thalamic activity is normal but the stimulus is depressed.

CLINICAL ELECTROENCEPHALOGRAPHY

In neurological investigations it is necessary to take simultaneous recordings from several leads to cover cortical activity over as wide an area as possible. This requires the use of multi-channel amplifiers with the electrodes placed on the scalp and connected in pairs to give antero-posterior and transverse cross-sections of activity in all areas.

For descriptive purposes the frequency spectrum from 1–30 cycles/second is as follows:

1–3·5	cycles/second	—delta	waves
4–7	,,	—theta	,,
8–13	,,	—alpha	,,
14–18	,,	—beta	,,
20–30	,,	—gamma	,,

It is the alpha rhythm of 8–13 cycles per second which predominates in the normal adult at rest, but there is a wide variation in the normal pattern between different individuals.

Under anæsthesia the individual variation disappears even in those patients who show abnormal records. This simplifies the study of the electroencephalogram during anæsthesia, as a single-channel machine with unilateral fronto-occipital leads can be used.

The Electroencephalogram under Anæsthesia

An early investigation of electroencephalographic activity during anæsthesia was carried out by Faulconer and his associates (Faulconer *et al.*, 1949) who demonstrated a correlation between depth of anæsthesia with nitrous oxide and changes in EEG activity.

Using ether, Courtin *et al.* (1950), showed that the electroencephalographic pattern varied with different levels of anæsthesia in a well-defined manner, and that it was possible to describe seven levels of anæsthesia on this basis (Fig. 2). The pattern present at any particular

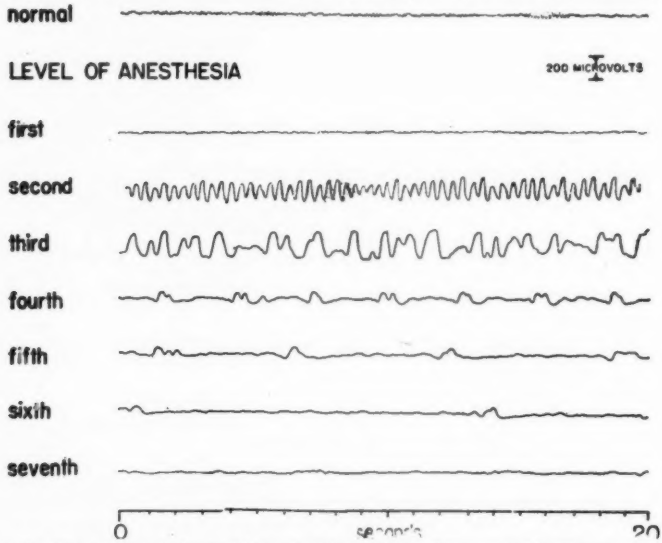

Fig. 2.—Electroencephalographic levels of anæsthesia (Nitrous oxide–Oxygen–Ether). (Reproduced from Courtin *et al.* (1950), by kind permission.)

time could be recognized as representative of one of these levels. As a measure of the depth of anæsthesia the electroencephalogram shows the direct effect of the drug in contrast to the accepted clinical signs of anæsthesia which are the peripheral effects of central depression.

An almost linear correlation between electroencephalographic level and arterial ether concentration was found from eighty-four observations (Faulconer, 1952; Bellville and Artusio, 1955). Ether in the presence of a nitrous oxide concentration exceeding 10 mg.% produced a deeper electroencephalographic level of anæsthesia than was obtained with the same concentration of ether alone.

Electroencephalographic activity under cyclopropane (Possati *et al.*, 1953) and sodium thiopentone (Kiersey *et al.*, 1951) has been studied, and well-defined electroencephalographic levels are demonstrated. The author has compared the steroid anæsthetic agent Viadril with sodium thiopentone, and the pattern sequence was found to be similar. Of other commonly used drugs, morphine, pethidine and muscle relaxants produce no effects on the electroencephalogram, when used in normal doses.

Effect of Anoxia on Electroencephalographic Activity

Many workers have shown, both in man and animals, that anoxia in the absence of anæsthesia produces marked alteration in the encephalogram (Sugar and Gerard, 1938; Gibbs *et al.*, 1940; Amyers *et al.*, 1953).

Under anæsthesia it can be shown experimentally (Beecher *et al.*, 1938) that there is little effect on cerebral activity until a level of 40% oxygen saturation in arterial blood is reached (in the presence of a normal carbon dioxide tension); below this level cortical depression rapidly supervenes. This is a marked fall of oxygen saturation; as it has long been accepted that cerebral cells are extremely sensitive to oxygen lack, the explanation may lie in a compensatory mechanism controlling the cerebral circulation. It can be shown that there is a reduced cerebral arteriovenous difference in states of anoxia. Assuming that oxygen requirements remain the same, this indicates an increase in total cerebral blood flow.

Carbon Dioxide Tension and Cerebral Activity

It is accepted that a high arterial carbon dioxide tension becomes a narcotizing agent and that this effect is potentiated by the presence of barbiturates and other anæsthetic agents. It has been shown, both in man and animals (Clowes *et al.*, 1953), that this depressant effect is reflected by alteration in electrical activity of the brain.

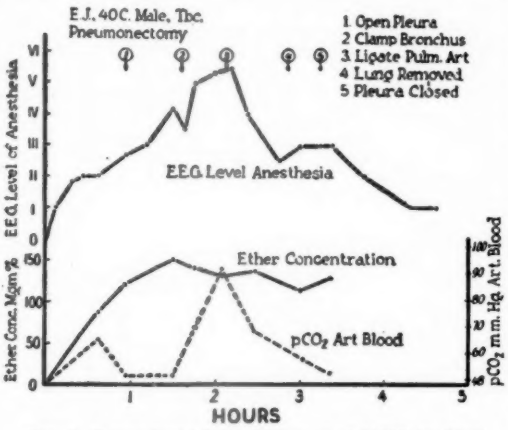

FIG. 3. (Reproduced from Clowes *et al.* (1953) by kind permission.)

The value of the electroencephalogram in demonstrating the depressant effect of carbon dioxide has been shown clinically in a patient undergoing pneumonectomy under ether anæsthesia (Fig. 3). The EEG showed the pattern of anæsthetic level IV, with a normal carbon dioxide tension. When the bronchus was clamped, leaving the vessels intact, the blood carbon dioxide tension rose rapidly to 94 mm.Hg and, in spite of a slight fall in blood ether concentration, the EEG pattern altered to level V and practically to level VI. Shortly after ligation of the pulmonary artery the tension of carbon dioxide fell from 94–68 mm.Hg and the EEG pattern returned to level III.

Effect of Hypotension

The EEG pattern under hypotensive conditions depends on the actual blood pressure and the rate of fall. At a rate of under 10 mm.Hg/min. a fall of 100 mm.Hg may produce no electroencephalographic change. Rapid, although smaller, decreases in blood pressure can produce slow, high amplitude waves or even temporary cessation of activity. These findings may be explained by assuming that cerebrovascular resistance is unable to accommodate to very rapid falls in blood pressure, and a fall in cerebral blood flow occurs. The resulting anoxæmia produces depression of the EEG; recovery occurs as the cerebrovascular resistance decreases, causing increased blood flow, even though blood pressure remains low. When the blood pressure is reduced slowly the cerebrovascular resistance may decrease as the blood pressure falls, so that cerebral blood flow remains constant and the EEG is not altered.

We have shown, using the EEG, that sodium thiopentone acts for a much more prolonged period under induced hypotension than in the normotensive state; in one patient where the systolic pressure had been reduced from 110–55 mm.Hg, 125 mg. of sodium thiopentone caused a depression from level I to level II which did not return to level I for thirty minutes.

Effect of Hypothermia

Reduction of body temperature to reduce oxygen requirements has become an accepted technique of anæsthesia. Little change occurs in cerebral activity until the temperature reaches 31°–35° C., when some decrease in amplitude and frequency occurs.

At 25° C. the voltage is further decreased. At 20° C. there is no appreciable activity in either parietal or occipital regions and only a slight wavering of the base line at 2 cycles/second in the frontal region.

Repeated cooling or prolonged maintenance at low temperatures does not alter the pattern. During rewarming no new rhythm appears and the changes of cooling appear in the reverse order but with a lag of 1° to 2° C. The return to normal EEG pattern confirms the clinical findings that no permanent brain damage is sustained at these low temperatures.

THE VALUE OF THE EEG IN CIRCULATORY ARREST (Bellville *et al.*, 1955*a*, *b*)

Following arrest of the circulation the first cells to suffer permanent damage are those of the cerebral cortex. It is recognized that if cardiac massage is to lead to a successful outcome an adequate circulation must be instituted within three minutes.

We have confirmed the value of the electroencephalogram in a case of cardiac arrest in an infant during thoracotomy under hypothermia. Fig. 4A shows the EEG pattern prior to circulatory arrest when the body temperature was 29° C. Within a period of 12 seconds following arrest virtually all electrical activity ceased (Fig. 4B) but activity could be restored to the pre-circulatory arrest pattern by cardiac massage (Fig. 4C). The interval between cessation of the circulation and alteration in pattern is rather longer than in other cases reported (Bellville *et al.*, 1955*a* and *b*), probably due to the reduction in oxygen requirement by the cortex at low body temperature. While it is possible to cut off the circulation in a patient at this body temperature for a period of 8 minutes without causing any permanent cerebral damage, it is interesting to note that cerebral electrical activity becomes negligible immediately the circulation ceases. Circulatory occlusion, in a patient at normal temperature,

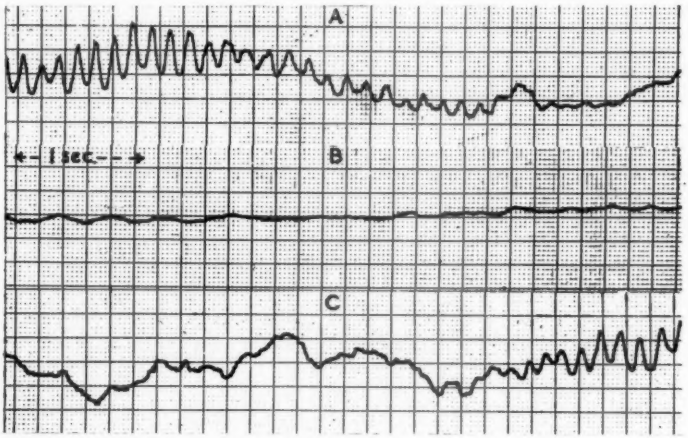

FIG. 4.

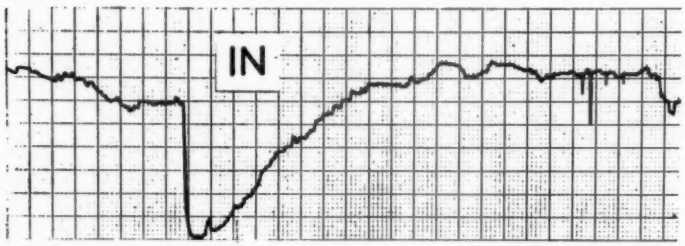

FIG. 5.

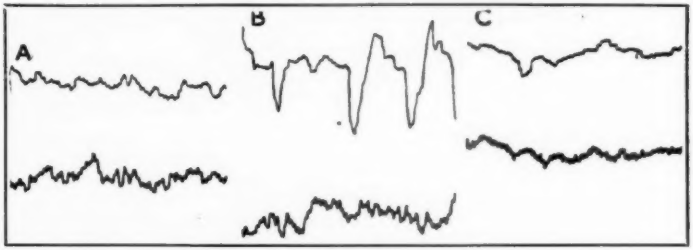

FIG. 6.

produces the same effect on the encephalogram, but in this case the changes are irreversible if present for more than a brief period. In the case reported the longest period of complete inactivity in the electroencephalogram was 1 minute 45 seconds.

The electroencephalographic changes in circulatory arrest are sufficiently rapid to allow the surgeon immediately to assess the efficiency of cardiac massage.

The sensitivity of the electroencephalogram during the cessation of the circulation has been demonstrated during the course of mitral valvotomy. During the brief period of occlusion of the orifice of the mitral valve the record becomes momentarily abnormal, but returns to the normal picture immediately the circulation is restored (Fig. 5). The reason for the alteration in EEG recording being even more rapid than in cases of cardiac arrest is not known.

We have also made use of the electroencephalogram to determine the adequacy of the circulation during operation on a carotid body tumour. Here we used a twin-channel machine, using fronto-occipital leads on each side. During the initial part of the operation the records were similar, as would be expected (Fig. 6A). A fall of blood pressure from 110–55 mm. Hg systolic, produced by Arfonad and posturing, in twelve minutes did not alter the pattern. During dissection of the tumour, with partial occlusion of the common carotid artery, the corresponding record became dominated by slow waves up to an amplitude of 50 microvolts (Fig. 6B). These resulted from anoxæmia. No additional anæsthetic drug had been administered nor was there any alteration in blood pressure, the record on the normal side remaining the same as at 6A. Application of the clamp to the common carotid for one minute produced increased cortical suppression in the affected hemisphere (Fig. 6c). Recovery did not occur during one minute following its removal. During the ten-minute period following ligation of the vessel an increase in cortical activity on the affected side occurred with loss of the periods of suppression, decrease of the high voltage low frequency waves and reappearance of fast activity.

Following operation this patient remained drowsy for a period much greater than would be expected from the total dosage of depressant drugs. The following day he complained of severe headache, confined to the affected side. Both these effects were probably the clinical manifestation of the period of cerebral anoxia. No permanent brain damage ensued, nor had this been expected from the brief duration electroencephalographic findings.

SUMMARY.—(1) The physiological basis for the electroencephalogram is described. (2) The value of encephalography in anæsthesia is described in relation to the usual anæsthetic agents. (3) The effects produced by anoxia, carbon dioxide, hypotension and hypothermia are discussed. (4) Cases are reported of the use of the electroencephalogram in various forms of circulatory disturbance.

The Role of Posture in Laminectomy [*Abridged*]

REGISTRARS' PRIZE ESSAY

By D. J. PEARCE, M.B., F.F.A.R.C.S., D.A.

TROUBLESOME hæmorrhage has always been a consistent feature during laminectomy, often making adequate exploration of the vertebral canal and nerve roots impossible. Hæmorrhage can occur at all stages of the operation: initially, from the superficial tissues and muscles and, later, from the cut spinous processes and laminæ and the epidural veins. The blood loss during operations on the spinal column and cord varies from 658 ml. to 992 ml. (Bonica and Lyter, 1951).

In the efforts to combat this problem many techniques have been used; originally local infiltration (Freiberg and Perlman, 1943) was carried out, but more often to obviate the deleterious effects of ether anæsthesia rather than to reduce blood loss. Other workers used spinal anæsthesia (Nitikman, 1945; Hunter, 1950), pointing out that the blood-pressure fall and degree of muscle relaxation provided ideal conditions. Similar arguments have been advanced in favour of epidural anæsthesia (Bromage, 1952). Further progress was made with the introduction of the hypotensive agents of the methonium series (Davison, 1950;

Enderby, 1950; Organe, 1950; Scurr, 1951) and Arfonad (Magill, Scurr, and Wyman, 195), although Wyman has pointed out the inconsistency of results with these methods. Oth r workers have shown that, despite the attenuation of bleeding from the superficial tissues w h the use of these drugs, considerable hæmorrhage could still occur from the deeper structu s (Rollason, 1953).

Closely associated with this is the problem of posture; for bilateral explorations of t e vertebral canal the prone position has been advocated (Pennybacker, 1950), providing th t an efficient suction apparatus is available to keep the operative field clear of blood. Th s disadvantage has caused many workers to adopt the lateral posture, so that blood tends o run out of the wound rather than collect in the depths of a cavity.

From our study of 80 cases of lumbar laminectomy it was evident that the operative co - ditions were extremely variable. The anæsthetic methods included spinal, epidural—wit h and without the addition of adrenaline hydrochloride solution—and general anæsthesia, th e latter with and without the use of hypotensive drugs. Both prone and lateral positions wer e employed. Even with the use of pentamethonium iodide or Arfonad, which in most case s considerably reduced bleeding from the superficial tissues, it was apparent that difficulty ha d often been experienced in identifying the disc lesion owing to troublesome hæmorrhage fro m the deeper structures. Comments such as, "Persistent ooze from the raw, bony surfaces", or, "Troublesome bleeding from epidural veins", were only too common in the anæsthetic notes. It was also noted that post-operative oozing from the wounds and hæmatoma formation occurred frequently. That the latter is a well-recognized complication is a fact also borne out by other workers (O'Connell, 1951). In view of the disappointing discrepancy in these results it was felt that a further study should be carried out.

Methods of Study

Since it was realized that the chief difficulty was venous oozing, the studies were directed towards the elimination of inferior vena caval compression, the cause of the congestion.

(1) *Anatomy of the venous drainage of the lumbar vertebræ and vertebral canal.*—The vertebral bodies contain and are surrounded by an extensive network of veins, forming a vast potential venous reservoir. All of these vessels, together with venous channels from the vertebræ themselves, drain into segmental intervertebral veins which accompany the spinal nerves through each foramen and thence to the lumbar veins. The drainage of the lumbar veins, of which there are five pairs, is variable. The third and fourth pairs end in the inferior vena cava, while the first and second pairs either drain into the inferior vena cava or the ascending lumbar vein. The latter is a vessel which passes upwards on the roots of the transverse processes, anastomosing with the ilio-lumbar vein below and connecting together the other lumbar veins; it also receives tributaries from the anterior external vertebral plexus. The fifth pair of lumbar veins drain into the ilio-lumbar veins.

(2) *Venous pressure measurements.*—Venous pressure measurements were taken from the lower end of the inferior vena cava by means of a cardiac catheter connected to a simple water manometer. Six series of results were obtained (Table I). In each case it was clearly

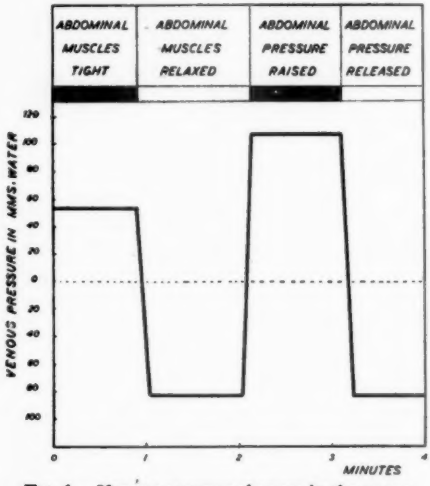

Fig. 1.—Venous pressure changes in the prone supported posture.

Table I.—Venous Pressure Changes in the Prone Supported Posture
(Maximum Readings in mm. H_2O)

Case No.	With abdomen hanging free	With abdomen compressed
1	10–25	170–200
2	45	180
3	0–15 0–10	300+
4	0–25	150
5	40	115
6	–80	110

demonstrated that pressure on the abdomen, sufficient to cause obstruction of the inferior vena cava, produced a remarkable rise of venous pressure, in some cases to more than 300 mm. H_2O. Even the slightest compression caused a rapid increase of 30–40 mm. H_2O, a rise of pressure probably large enough to distend the thin-walled epidural veins.

In comparing the different postures it was found that the lowest corrected venous pressure (−80 to +45 mm. H_2O) occurred in the prone position with a large bloc

under the chest and several small sandbags under each anterior superior iliac spine; by using muscle relaxants the abdominal wall was allowed to hang quite freely and clear of the table surface (Fig. 1). Using controlled respiration, however, it was essential that no build-up of carbon dioxide occurred nor increase of pressure during the expiratory phase, as this caused a rapid rise of venous pressure. With the return of spontaneous respiration and contraction of the abdominal muscles an average increase of pressure of approximately 100 mm. H_2O occurred and this rose even higher if the patient was allowed to strain.

(3) *Histology of the epidural veins.*—These veins are thin-walled (Franklin, 1937), contain little or no muscle tissue, and valves are present in only a few of the smaller channels, so that the slightest rise in venous pressure will cause distension.

(4) *Dye injection studies in the cadaver.*—Harris (1941) has drawn attention to the original papers describing the anatomy of the spinal and vertebral veins. The classical paper by Batson (1940) on the metastatic spread of prostatic carcinoma re-emphasized the rich anastomoses of the vertebral plexuses with the inferior vena cava. Furthermore, from his experiments on cadavers and live monkeys he was able to show that a rise of intra-abdominal pressure, sufficient to produce compression of the inferior vena cava, caused radio-opaque dyestuffs to pass into the vertebral system of veins.

This experiment was carried out in the human cadaver, colloidal barium sulphate solution being injected through a cannula in the deep dorsal vein of the penis and serial X-ray films taken. Without obstruction the dye flowed easily along the inferior vena cava (Fig. 2), but when this was ligated the barium was seen to pass into the anastomotic channels (Fig. 3).

FIG. 2.—Normal flow of radio-opaque dye along the i.v.c. Antero-posterior view.

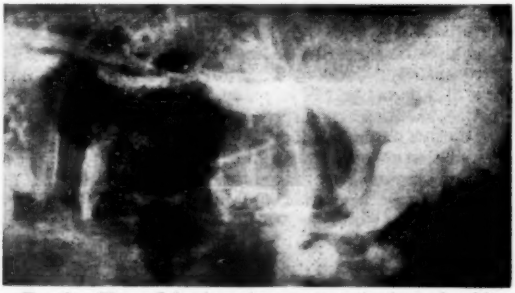

FIG. 3.—Flow of dye into the anastomotic channels with the i.v.c. ligated. Lateral view.

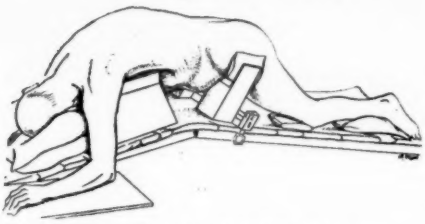

FIG. 4.—Position of patient for laminectomy.

From these results it became obvious that compression of the abdomen and inferior vena cava during laminectomy should be avoided at all costs, in order to eliminate completely the possibility of hæmorrhage from engorged epidural veins. It was also felt that reduction of hæmorrhage from the superficial tissues could best be achieved by infiltration with 1/250,000 adrenaline hydrochloride solution.

TECHNIQUE EMPLOYED

The standard principles of general anæsthesia are observed, using sodium thiopentone, nitrous oxide and oxygen, supplemented by pethidine and muscle relaxants as the anæsthetic agents. In these cases suxamethonium chloride, in drip form, has been used to provide muscle relaxation. Endotracheal intubation with a cuffed oral Magill tube is used in all cases to ensure complete control of the airway and to prevent aspiration of any regurgitated gastric fluids during positioning on the table.

The patient is placed in the prone posture with a large supporting block under the upper part of the chest and adjustable, well-padded supports under the anterior superior iliac spines (Fig. 4). In this way the abdomen is allowed to hang freely. The legs are lowered

slightly and the knees and ankles supported by soft pads. The hands are allowed to rest on stools, placed on each side of the operating table. A head-down posture is never allowed in patients who have recently had a myelogram.

To reduce bleeding from the superficial tissues a solution of 0·25% lignocaine hydrochloride with 1/250,000 adrenaline is used, according to the method described by the late Dr. Rait-Smith (1949) for chordotomy. Using a strictly aseptic technique, approximately 10 ml. of solution are injected down to the root of each lumbar transverse process in a fan-wise direction two fingerbreadths from the mid-line. In this way a barrier of solution is deposited in the muscles and in the angle formed between the transverse process and the lamina of the vertebra. Three spaces above and three spaces below the suspected site of the disc lesion are infiltrated on each side. Finally, a superficial mid-line skin wheal is raised at the site of the surgical incision. The total volume of solution used is 120–150 ml. The infiltration can be carried out either by the anæsthetist or the surgeon, as conditions permit. In case of superficial œdema caused by the infiltration, a scratch mark should be left at a predetermined site as a landmark for the benefit of the surgeon.

In some of the cases chlorpromazine hydrochloride was used in order to obtain the reversal of the adrenaline pressor reflex, but no real difference was noted in the results and it is not considered an essential part of the technique.

Results

A further 25 cases of laminectomy have been carried out using this technique. In all of them the operating conditions have been so outstanding that the use of Spencer-Wells forceps and diathermy has been entirely unnecessary and the suction apparatus rarely required. An extremely thorough exploration of the vertebral canal and nerve roots has been possible and yet, in many instances, the actual operating time has been reduced to thirty minutes. It was thought at first that the lack of flexion of the lumbar vertebræ would be a disadvantage, but in practice this is not so.

Also, the increase in the time allowed for the induction of anæsthesia, positioning and local infiltration has been more than offset by the reduction in the actual operating time.

Apart from one post-operative chest infection no complications have occurred. In each case the wound has healed by first intention and no hæmatomata or sero-sanguineous exudates have been encountered. The addition of 0·25% lignocaine hydrochloride to the solution used for infiltration appears to provide more immediate post-operative relief.

Although this series has been based on cases of prolapsed intervertebral disc, it follows, nevertheless, that this method can be employed in laminectomy for all other causes, except those in which sepsis is thought to be present.

Summary.—(1) The anæsthetic techniques employed in laminectomy in an attempt to provide a bloodless field for the surgeon are reviewed briefly and the discrepancy in operating conditions noted in a series of eighty cases. (2) The role of posture is studied by means of venous pressure measurements from the inferior vena cava, the histology of the epidural veins and dye-injection studies in the cadaver. (3) The method of anæsthesia used successfully in a further series of 25 cases of laminectomy is described.

Acknowledgments.—I should like to thank Dr. J. B. Wyman for his help in producing this paper, also Mr. H. E. Harding, the consultant surgeon.

To Mr. P. A. King, Mr. F. C. Hoyte, Mr. G. Keen, Dr. J. R. E. Jenkins, Dr. P. Cliffe, the members of the Departments of Pathology and Medical Photography, and to Miss Howeth of the X-ray Department (all of Westminster Hospital) I owe a special debt for their very ready assistance with many of the investigations.

BOOK REVIEWS

Health in Industry: A Contribution to the Study of Sickness Absence: Experience in London Transport. (Pp. 177; illustrated. 35s.) London: Butterworth & Co. Publishers Ltd., on behalf of the London Transport Executive. 1956.

The late Lord Horder, in a foreword to this valuable study of sickness-absence statistics, gives a clear account of its origins. In the 1930's allegations had been made that the work of bus drivers and conductors was unduly exacting and injurious to their health. The matter was investigated by the Industrial Health Research Board of the Medical Research Council and Bradford Hill's report[1] was published in 1937. The statistical data available at the time were limited and incomplete, and the report was based on comparisons between illnesses of bus drivers and conductors lasting fifteen days or more in the years 1933–35, and those of tram drivers for the same period. As a result of conferences between representatives of the London Passenger Transport Board, the Transport and General Workers' Union and the Medical Research Council, the Board decided to strengthen its medical service and to make more satisfactory arrangements for recording particulars of sickness absence of members of its staff. It authorized the establishment of a Central Record of Staff Statistics, using punched cards, and records by this system have now been available since January 1948.

Dr. L. G. Norman, the Chief Medical Officer, and Mr. F. H. Spratling, Staff Administration Officer, describe how the records have been built up and how the data have been subdivided into broad diagnostic groups. It is encouraging to read that they are of the opinion that the diagnoses shown on medical certificates given by general practitioners are precise enough to justify their use as a basis for classification. A high degree of agreement has been found between the diagnoses by the London Transport doctors and those by the general practitioners.

Mr. F. H. Spratling contributes a closely reasoned account of the principles and methods followed in compilation of the statistics, together with explanations as to how they are to be used for comparison with other occupational groups. The major portion of the book (145 pages) is devoted to tables showing the actual and expected sickness-absence records in four main groups: (i) drivers and male conductors, central buses 1949–52; (ii) motormen and guards, London Transport railways 1950–52; (iii) male workshop staff, bus overhaul works 1949–52, and (iv) clerical and technical staff 1950–52.

It is not difficult to agree with the authors that the study of the incidence of sickness and disease, in all its forms, is of the highest importance; and with their hope that the London Transport statistics will be used by others who work in this field in order to make purposeful studies of the incidence of sickness absence in different occupations and employments. It is rather a pity that the reader is left to make his or her own conclusions as to whether this first batch of figures shows significant differences between groups or suggests the presence of occupational factors. The effect of age on sickness, however, is clearly shown.

The London Transport Executive and its staff are to be congratulated on their determined effort to put sickness-absence recording on a sound basis.

Anæsthetic Accidents: The Complications of General and Regional Anæsthesia. By V. Keating, M.B., B.Ch., D.A., F.F.A. R.C.S. (Pp. vi + 261; illustrated. 25s.) London: Lloyd-Luke (Medical Books) Ltd. 1956.

Much of every anæsthetist's training and practice is devoted to the prevention of the accidents and complications which may so easily occur as the result of his administrations.

Any worth-while treatise on this subject must therefore embrace practically the whole range of the specialty. It must also consider at length the fundamental physiological processes of the body and how they may be disturbed by anæsthetic drugs and procedures, for only by a full understanding of these mechanisms may further disasters be avoided.

These criteria are fulfilled in this excellent treatise, which is far more than a mere chronicle of mishaps culled from the scattered literature. These many collected reports on the untoward sequelæ of every type of anæsthetic would in themselves make instructive reading, but their value is greatly enhanced by the author's wise comments on them. Much of our knowledge of physiology and pharmacology is derived from animal experimentation, but Dr. Keating is well aware that the conclusions drawn from such experiments are not always applicable to man in their entirety. He is careful to point out where our knowledge is incomplete, and here he is not afraid to make constructive suggestions based on his clinical experience. In the Preface this book is described as "an attempt to review the causes and to

indicate the possible prevention of . . . anæsthetic accidents". In this purpose the author has succeeded admirably and this well-produced little book deserves to be widely read.

The Care of the Expectant Mother. By Josephine Barnes, M.A., D.M.Oxon., M.R.C.P. London, F.R.C.S.Eng., F.R.C.O.G. (Pp. x + 270; illustrated. 30s.) London: Pitman Medical Publishing Co. Ltd. 1956.

The title of this excellent book is somewhat of a misnomer, for it gives the impression that here is merely yet another advisory handbook for the woman expecting her first baby. In fact it is a scientific textbook designed specifically for "all who undertake the management of pregnancy", and being written from a very practical angle throughout, it forms an excellent general guide to this subject.

The most revolutionary change in obstetric practice in the past thirty years has been in antenatal care, and there is little doubt that the dramatic improvement during that period in maternal and fœtal mortality is due mainly to careful medical supervision during pregnancy. Miss Barnes' book, based largely on clinical lectures to students and pupil midwives, gives the most complete account to date of how a pregnant woman should be cared for from conception to delivery. Almost every conceivable aspect of the subject is covered, from prenatal advice to radiological pelvimetry, and all are described successively and in a practical common-sense manner.

In handbooks of this nature, a certain amount of dogmatism is inevitable, but some of the author's statements are possibly too emphatic. Few obstetricians, for example, will agree that "abdominal examination is not strictly necessary before the 32nd week," or that it is a good thing to use Hegar's sign as a test for pregnancy. It is also doubtful whether massaging the breasts for two months to express colostrum before delivery may not do more harm than good, and the dangers of radiography to the fœtal gonads require constant emphasis to avoid unnecessary exposure. The book deserves general praise for its practical attention to the details of normal and abnormal pregnancy, and as such it will be invaluable not only to senior students and midwife teachers, but more particularly to general practitioner obstetricians, who will find here their complete vade-mecum.

Operative Surgery. Editors: Charles Rob, M.C., M.Chir., F.R.C.S., and Rodney Smith, M.S., F.R.C.S. In 8 volumes and index. (Volumes 1 and 2. Volume 1 Introductory, Surgery of Trauma, Abdomen (part); Volume 2 Abdomen (completion); illustrated. £5 10s. per volume.) London: Butterworth & Co. Publishers Ltd. 1956.

One has merely to glance at and handle these first two volumes of this projected 8-volume work to recognize that it has been conceived and produced on a noble scale. And the first task of any reviewer must be to congratulate both the editors and the publishers on this. In their introduction, the editors explain the principles they have followed. Operations are best learnt by watching, and therefore the principal emphasis of any operative surgery textbook should be visual. The text should be minimal, and largely explanatory of special points and difficulties. The work is chiefly intended for surgeons in training, surgeons working in an isolated community, and experienced surgeons called on to operate in an unfamiliar field. The potential surgical public is, therefore, a large one. The editors have chosen with care their contributors (judging by the contributors to these two volumes their choice will command general respect), and having done so they have largely relied on their judgment.

Three subjects are dealt with in the two volumes now under review—Part I General Technique, Part II the Surgery of Trauma and Part III the Abdomen. Part I contains much that might be compulsory reading for house surgeons, e.g. the choice of ligature material, the technique of intravenous infusions, and the tying of knots; the author of the latter is surely a fisherman. The chapters on the Burst Abdomen and Radium Needle Insertion seem, however, rather out of place. Part II consists of an excellent series of articles on the treatment of trauma. Relatively small points of criticism are that only surgery is considered in the treatment of heart tamponade and no mention is made of aspiration; and that the débridement of wounds is stated to be contra-indicated if more than eight hours have elapsed since the wound was inflicted. In Part III on the abdomen, one notes the article by Tanner on Gastrectomy with all his numerous tips for dealing with difficult ulcers. And your reviewer found the article by Milnes Walker on porta-caval anastomosis a useful test, since it is not an operation he has performed or seen performed, and he would be much more confident in performing it now. In the chapter on partial hepatectomy, however, one is a little surprised not to see right lobe hepatectomy described as well as left lobe hepatectomy.

Full judgment on the work must obviously await the appearance of the further six volumes. But first reactions are that the editors and publishers are establishing their case, and one ventures the prophecy that the work will have a big sale throughout the world and in so doing will advance still further the prestige of Great Britain and of European culture in general.

Clinical Section

President—Sir HENEAGE OGILVIE, K.B.E., D.M., M.Ch., F.R.C.S.

The Solution of a Surgical Dilemma.—GEOFFREY FLAVELL, F.R.C.S., M.R.C.P.

The patient is a police inspector aged 43. In 1933 he had a left spontaneous pneumothorax, which recurred in 1937. Mass miniature radiography in 1953 revealed a very large emphysematous bulla at the apex of his right lung occupying much of the pleural space. The left apex was hypertranslucent (Fig. 1). I advised excision of the air cyst but as he was symptom-

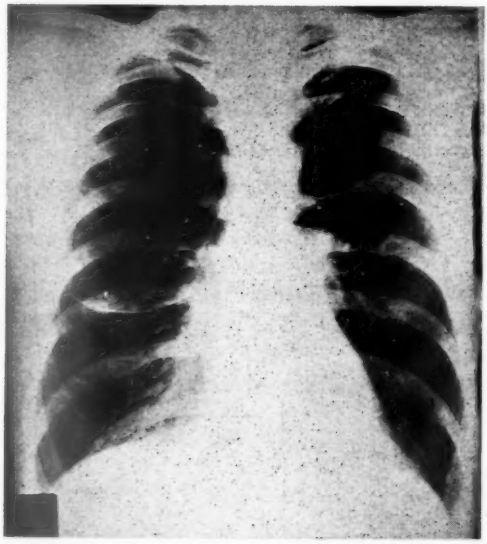

FIG. 1 (January 1955).—The initial state of the patient's chest with the whole of the upper part of the right lung displaced by two enormous bullæ. Note the hypertranslucency also present at the left apex.

less he refused, but he continued to attend the follow-up clinic at six-monthly intervals. The bulla did not increase in size. He remained well until August 1955 when for the first time he noticed breathlessness, and a little later developed a cough productive of purulent sputum. This was followed by fever and hæmoptysis. X-rays of his chest revealed a patchy opacity spreading over most of the upper lobe of the left lung (Fig. 2). At first this was thought likely to be inflammatory, and following antibiotic therapy it resolved largely—*but not wholly*. As a diagnosis of "unresolved pneumonia" is unacceptable the patient was bronchoscoped, and a bronchial carcinoma was found growing from the left upper lobe orifice.

Left pneumonectomy was out of the question; and even if upper lobectomy had been technically possible it could not have been undertaken with so much of the opposite lung compressed by an enormous alveolar cyst. It was therefore decided:

(1) to treat the growth with deep X-rays in order to render lobectomy feasible, and

(2) to operate first upon the right lung to remove the bulla and so to secure maximum efficiency;

(3) then to operate on the left lung and remove the growth.

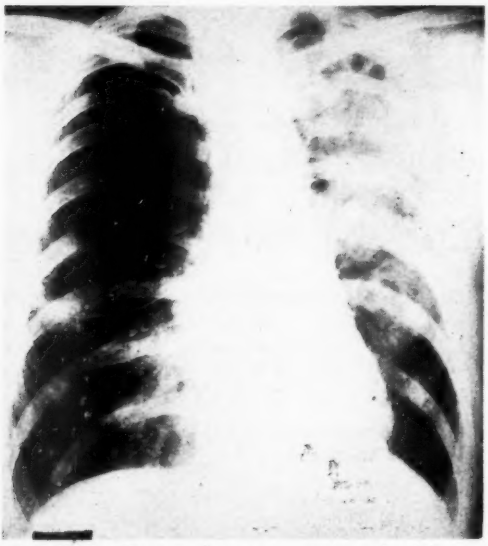

FIG. 2 (October 1955).—The opacity now present at the left apex is due to infection occurring distal to bronchial obstruction caused by a neoplasm.

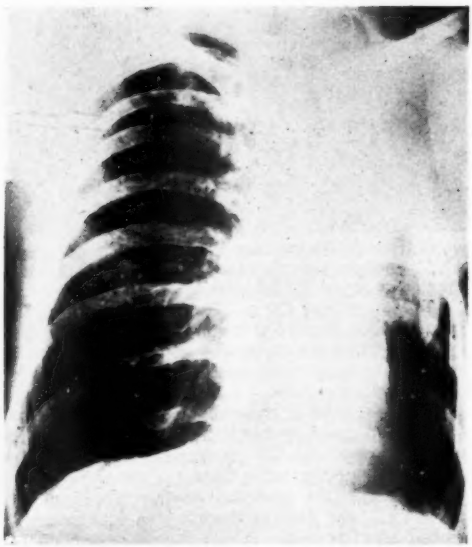

FIG. 3 (June 1956).—The bullæ have been removed from the right lung which is now totally re-expanded. The left upper lobe containing the neoplasm has been removed and an apical thoracoplasty performed to preserve the left lower lobe from increasing emphysema.

By the beginning of February 1956 bronchoscopy showed the growth to have regressed and to be now operable by lobectomy. On 6.2.56 two very large bullæ with a volume of about 1 litre were excised from the upper lobe of the right lung, the anterior segment of which was spared. Post-operatively so much air leakage occurred from the raw area of emphysematous lung left behind that the patient developed a *tension pneumothorax* in spite of two drainage tubes attached to continuous suction pumps; and it was not until four pumps were put in line that the right lung completely re-expanded to fill the pleural cavity. Following this operation dyspnœa was wholly relieved—in fact the patient has never been breathless since—and bronchospirometric studies showed his respiratory efficiency to have improved by 50%.

On 20.2.56 the left chest was opened, and the upper lobe of the lung removed without difficulty. On section, residual strands of polygonal cell carcinoma were found beneath the bronchial mucosa, but no growth reached to the cut end of the bronchus or was found in the regional glands. During the next few weeks the left lower lobe showed signs of increasing emphysema, so on 19.3.56 a left apical thoracoplasty was performed (with removal of the 2nd, 3rd and 4th ribs) to obliterate dead space and prevent over-expansion of the lower lobe (Fig. 3).

By June the patient was completely well, working, and suffering not at all from breathlessness. Bronchoscopy showed the site of amputation healthy with no evidence of recurrence.

In September he complained of a persistent occipital headache and, suspecting a metastasis, I referred him to my neurosurgical colleague Mr. J. Crawford. On 12.9.56 ventriculography confirmed this diagnosis and on the same day Mr. Crawford performed a posterior fossa craniotomy and removed a well-defined secondary deposit of bronchial carcinoma 3×3×2 cm. from the right lobe of the cerebellum. There was no evidence of any other deposits.

The patient was ambulant two weeks after operation and has made an uninterrupted recovery.

The following cases were also shown:

Chronic Lymphatic Leukæmia Treated with C.B. 1348.—Dr. R. J. HARRISON and Dr. D. A. G. DALTON.

Coronary Insufficiency: Implantation of Internal Mammary Artery.—Dr. J. C. FIRTH (for Mr. C. E. DREW and Dr. R. J. HARRISON).

Mitral Stenosis—Hæmosiderosis, Ossified Pulmonary Nodules—Valvotomy.—Dr. R. J. HARRISON and Mr. C. E. DREW.

Sarcoma of Leg.—Mr. L. DE JODE (for Mr. HERMON TAYLOR).

Spontaneous Hæmopneumothorax.—Dr. B. B. REISS (for Dr. R. J. HARRISON).

Two Cases of Spontaneous Rupture of the Spleen.—Dr. G. H. LUCAS (for Mr. W. D. PARK).

[*December* 14, 1956]

The following cases were shown:

Subdural Hæmatoma Referred as a Mental Case.—Dr. RICHARD ASHER.

Allergic Rheumatism, with Pulmonary Infiltration.—Dr. K. P. BALL.

? Collagen Disease. ? Atypical Virus Meningitis.—Dr. IAN FERGUSSON (for Dr. GERALD SLOT).

Long-standing Vascular Renal Tumour associated with Malignant Hypertension.—Dr. D. N. PHEAR (for Dr. K. P. BALL).

Solitary Actinomycosis of the Ulna.—Mr. G. S. PLAUT (for Mr. W. H. GERVIS).

Carcinoma of Stomach and Chronic Pancreatitis treated by Partial Gastrectomy and Pancreatico-Duodenectomy.—Mr. J. O. ROBINSON (for Mr. B. H. PAGE).

Scleroderma.—Dr. S. SEN (for Dr. GERALD SLOT).

Cushing's Syndrome—Surgical Aspects.—Mr. NORMAN C. TANNER and Dr. R. J. HARRISON.

Achalasia with a large Œsophageal Diverticulum.—Miss M. C. WATERFALL.

DISCUSSION: LEPTOSPIROSIS IN MALAYA

Lt.-Col. D. G. Levis:

Leptospirosis among Troops Operating in Malaya during 1954 *and* 1955

Introduction.—Leptospirosis is of widespread occurrence throughout the world [1]. This has perhaps not always been as well appreciated as it might have been. The variability of the clinical picture and the large number of distinct antigenic strains of leptospiræ responsible may perhaps have come as a surprise to those of us whose concept of the disease had hitherto been that of the severe illness originally described by Weil in 1886. Table I gives some idea of the variability of the disease and its nomenclature and, suggesting as it does a varied occupational ætiology and distribution, should remind us to suspect leptospirosis as being a cause of febrile disorders in many parts of the world.

TABLE I.—NOMENCLATURE: LEPTOSPIROSIS

Name	Infecting Leptospira
Weil's disease	*L. icterohæmorrhagiæ*
Canicola fever	*L. canicola*
Swineherds' disease	*L. pomona*
Mud/slime/water fever	*L. grippotyphosa*
Indonesian Weil's disease	*L. bataviæ*
Sejroe fever	*L. sejroe*
Seven-day fever	*L. hebdomadis*
Spirochætosis febrilis	*L. pyrogenes*
Cane fever	*L. australis A*

All these illnesses are generally characterized by fever, headache, myalgia and conjunctival injection but the hæmorrhagic, icteric and other prominent features of the classical disease may be lacking and there are often real difficulties in making a confident clinical diagnosis. In 1945 Buckland and Stuart reported cases of suspected Weil's disease among troops operating in N.W. Europe whose blood serum agglutinated with *L. sejroe* or *L. grippotyphosa* whilst giving no reaction to *L. icterohæmorrhagiæ* [2]. In 1949 Mackay-Dick and Watts were calling for an increased awareness of the manifestations of canicola fever in Germany [3]. In 1951 it was coming to be appreciated in Malaya that leptospiral infections with types other than *L. icterohæmorrhagiæ* were probably occurring in increasing numbers among troops engaged in jungle operations. The existence of leptospirosis in Malaya was, of course, known as a result of work by Fletcher in 1928. He demonstrated infection in man, dogs and various species of rats. He also showed the presence in human cases of *L. icterohæmorrhagiæ*, of several strains of *L. autumnalis* and *L. pyrogenes*. There were also others whose identity was not established at the time [4].

Military experience in 1954 and 1955 in Malaya suggested that infection with *L. icterohæmorrhagiæ* was the exception rather than the rule; and that leptospirosis could and did present a varied clinical picture. Unless it was specifically investigated as a cause of febrile illness it was likely to be missed and confusion with conditions such as dengue and scrub typhus was likely to occur.

Malaya in the two years 1954 and 1955 produced a certain total of 333 cases of leptospirosis from a military population which, over the period, remained virtually constant in size, composition and distribution. Leptospirosis is not a new disease to military populations.

The War of 1914–18 produced cases in what was described as mildly epidemic form in France and Flanders amongst both British and German troops. The majority of these appeared to be due to *L. icterohæmorrhagiæ* [5]. Operations in Europe in 1944–45 produced small outbreaks but the occurrence of other strains was noted [6, 2]. From a study

of available statistics, however, at no time during the whole of the 1939–45 War was anything approaching the number of cases which occurred in Malaya in 1954 and 1955 reported in any theatre: or indeed from all the British and Dominion troops engaged during the whole period. It was felt therefore that the Malayan experience of 1954 and 1955 was worthy of a closer study.

The pattern of incidence.—During 1954, 198 cases of leptospirosis from troops of all nationalities were admitted to military hospitals in Malaya: in 1955 this figure declined slightly to 135. These figures constituted 2·1% and 1·6% respectively of all admissions.

The mortality from the disease was low. There were only two deaths in the two-year period that could be confidently ascribed to leptospirosis. Many patients were, however, gravely ill; the majority were of mild to moderate severity and were incapacitated for about three weeks.

During the two-year period there was only one instance of the same individual contracting the disease twice. In this case the first infection was in April 1954, the second infection occurring in July of the same year. Between infections the individual remained well and at duty.

The temporal distribution of the cases in Malaya is shown in Fig. 1. It will be noted that cases occurred throughout the year. The apparent peaks of incidence were due to small outbreaks occurring in units operating in areas where experience showed a high endemicity.

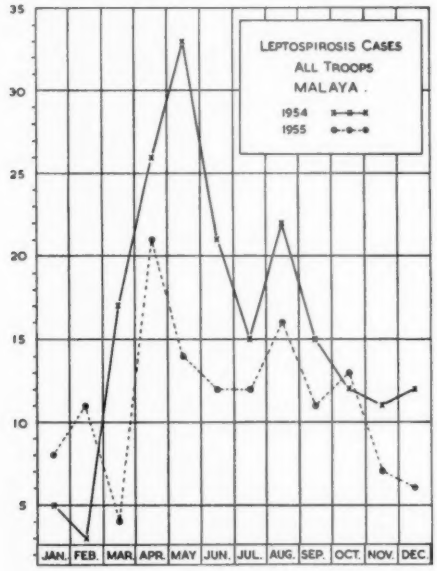

FIG. 1.

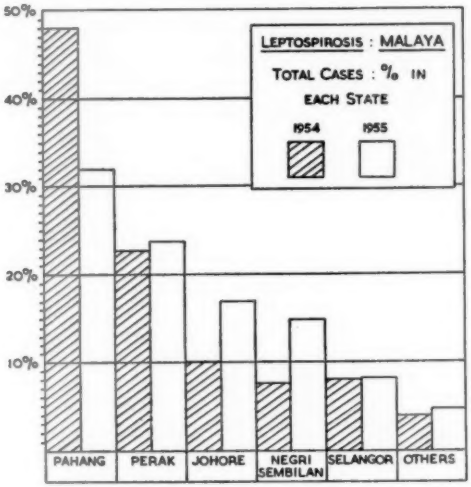
Although no convincing relationship to weather conditions was discoverable it was noted that the cases in Malaya were perhaps more obvious after a wet spell had occurred after a period of relative drought.



Australian workers have reported that in Queensland, which has an annual average rainfall of 60 in., cases of cane fever (*L. australis A*) generally showed an increase at the time of the peak rainfall (January, March) [7].

Geographical distribution.—When this was studied it was apparent that cases of leptospirosis could arise in nearly every State in Malaya. The number of the troops operating in each State varied with operational needs but when this number was studied against the number of cases of leptospirosis reported it became apparent that in at least two States there were areas where the endemicity of the disease was high, particularly the west central area of Pahang and the central area of Perak. There was a smaller and

rather subsidiary area about 10 miles out of Kuala Lumpur in Selangor, but it only attracted passing attention as operations therein were not continuous.

The existence of the disease in Perak was well known as a result of Fletcher's observations in 1928 but it was not until late 1953 that attention was focused on Pahang when a sharp outbreak occurred among British troops operating in the west central area of that State [12]. Fig. 2 shows the percentage distribution of cases of leptospirosis over the two-year period in each State.

In Trengganu and Malacca the number of troops in each State was almost negligible as they had been freed of trouble. The number operating in Kedah was small and in the main, Malay troops, while in Kelantan, apart from field engineer activities by a small unit, there was none. One feels fairly confident in saying, however, that, if larger numbers had been engaged in these States and operations had been extensive, cases of leptospirosis would have been noticeable.

OTHERS = KELANTAN, KEDAH, TRENGGANU, MALACCA, PROVINCE WELLESLEY.

FIG. 2.

It was the west central area of Pahang which had the evil reputation and no less than four British units at one time or other suffered in the same area. The high endemicity of this area was supported by the experience of two British units of equal size which performed almost identical operations in west central Pahang and Selangor having relieved each other. The attack rate for each was low while in Selangor, but increased sharply shortly after entry into Pahang. This observation can be underlined by the fact that the operations in Selangor entailed extensive patrolling of swamps which provided suitable opportunity for the contraction of infection. It occurred, but only sporadically.

Operational conditions and the distribution of cases amongst the troops at risk.—These two points may conveniently be discussed together. The following types of troops were engaged over the two-year period: British, Gurkhas and Malays who each formed a group of equivalent size; one battalion of Africans and one of Fijians, each of about the same size.

The administrative troops were based on the larger towns and worked from some permanent accommodation and never entered the jungle; the Armoured Corps had duties which, in the main, restricted them to road patrolling and convoy work with an occasional foray into the jungle. They were based on larger centres but had squadrons detached to the smaller country towns. The operational infantry operated as companies from semi-permanent camps in relation to the jungle fringe. From here they worked as small patrols returning to their company base after varying intervals to rest and refit before going out again. After a certain period each infantry unit would be withdrawn from jungle operations for a period of retraining in a major centre. The jungle work therefore fell on the infantry and the operations entailed prolonged and extensive patrolling, operations being

in primary or secondary jungle, scrub and swamp. While on patrol, troops lived on what they could carry or were maintained by a system of air supply. Water was found locally and instructions were that it should be boiled for tea or sterilized by individual outfits before drinking. In base camps and at unit H.Q.s fixed supplies were provided with filtration and chlorination under R.E. or unit arrangements. There is no doubt, however, that standards of water purification were uneven and patrols obtained water from indifferent sources. Washing facilities were primitive on patrol and it was not until return to base that individuals could achieve total skin cleanliness. The skin of the patrolling infantryman was rarely dry; sweat, rain, or both saw to that. Scratches and abrasions were inevitable in the thick secondary jungle where every kind of bush, creeper, thorn and bamboo abounded. Skin sepsis and fungus infections were encouraged by and flourished under such conditions. Strict insistence by regimental officers upon the prophylactic measures recommended could and did keep the skin troubles down, but they were there all the time.

The skin of the British soldier, particularly in the newly-arrived units, was liable to damage and infection; the Fijians generally had a high attendance on sick parades for minor skin troubles; the Gurkhas, Malays and Africans were affected but to a much lesser extent.

Such then were the general conditions under which troops of five nationalities operated in Malaya.

The leptospirosis experience of each group is given in Table II.

TABLE II.—DISTRIBUTION OF CASES BY RACE AND ROLE*

Role	British		Gurkhas		Malays		Fijians		Africans		Total
	1954–1955		1954–1955		1954–1955		1954–1955		1954–1955		1954–1955
Operational infantry ..	145	71	26	29	0	3	5	7	0	5	291
Others	14	14	2	5	4	1	—	—	—	—	40
Totals	159	85	28	34	4	4	5	7	0	5	331
Attack rate all troops per 1,000 per year ..	12·2		6·5	2·9	3·6	0·3	0·3	6·2	8·7	—	6·2	9·2

*This table does not include 1 Chinese liaison officer and 1 Dyak tracker who were attached to operational infantry.

Table II shows clearly that it was the operational infantry that sustained the majority of cases: the urban-based troops escaped lightly. When approximate attack rates per 1,000 men at risk were considered it was the British infantryman who suffered most, followed by the Gurkhas and the Fijians. Of all troops engaged, operational infantry or other, the soldier recruited in the country—the Malay—suffered relatively little.

It was first and foremost a disease of the jungle with the occurrence of sporadic cases in major urban centres or the more developed rural areas.

It is true that each of the areas noted as having a high endemicity contained a major British unit throughout the two-year period but, even after due allowance was made for this, the incidence among the British troops was still more noticeable. A Malay unit operated in west central Pahang simultaneously with a British unit over the period. They operated under identical conditions and in areas where leptospirosis was known to occur and yet the cases in this group were virtually nil. Taken overall, the number of cases of unexplained fever treated in the unit sick bays of Malay regiments was extremely small, as was the number admitted to hospitals for the same reason. Even if allowance is made that leptospirosis showed itself in its mildest form and passed unrecognized it is still considered that Malay soldiers were never seriously affected by leptospirosis. It is uncertain how far this reasoning can be applied to Fijians and Africans (both small groups) but it is possible that cases of fever with rapid recovery in both groups—which were retained in unit lines to a slightly larger extent than in the Malay group—may have included unrecognized cases of leptospirosis. The Africans operated in west central Pahang. The Fijians were in Johore.

The third big group, the Gurkhas, had a much lower incidence than the British. They may have been luckier in their operational areas. A group of cases (about six) did occur in a major infantry unit in an area of Selangor near Kuala Lumpur in 1955 and, for its size, the non-operational group of Gurkhas located mainly in well-developed camps and areas produced an attack rate nearly equivalent to the British non-operational group (approximately 2·3 per 1,000 per year Gurkha: 3 per 1,000 per year British). Gurkha susceptibility is hard to assess with any certainty.

Source of infection.—At various times animals such as rats, cattle, pigs and dogs have all been shown to harbour various strains of leptospiræ.

In Malaya there is a very large rodent population and at least three species of rat which

inhabit the primary jungle have been shown to be infected with leptospirosis [8]. In late 1955 two further species from camps in west central Pahang were also incriminated [9]. These last two were not primary forest rats by habit. They preferred secondary jungle, grassland or scrub, being abundant in the latter and in ladangs and areas of temporary cultivation. Rats therefore were in close relationship to the infantryman in his temporary jungle camps, his patrolling and ambush areas in the primary and secondary jungle and in his base camps.

Wild pigs in Malaya were also no strangers to the patrolling infantry, dogs were numerous in the ladangs and kampongs and certain of the British battalions employed tracker dogs with soldier handlers. Pig and buffalo wallows were far from rare. Possible additional sources of infection were not hard to find and mud, slime and water met in paddy-fields, swamps, rivers and streams were available to be contaminated.

Certain leptospiræ have recently been shown by Australian workers to remain viable for up to fifteen days in damp and acid soil [10]. Conditions in the Malayan jungles were probably equally suitable. A variety of leptospiræ were identified in Malaya from infections occurring among troops. There was no pattern to their distribution, west central Pahang provided a wide range and among the identifications carried out, icterohæmorrhagiæ ranked low in frequency. No cases were reported specifically among unit dog handlers, but that the dogs could at times be infected was appreciated. In only one patient was the infecting leptospira identified as *L. pomona* although wild pigs abounded in the scrub and swamp.

It is considered therefore that the main source of infection lay in the rodent population and that these were to be found in the temporary camps in the jungle, deeply buried ladangs, remote or deserted kampongs, deserted areas of cultivation or the swampy scrub encountered on patrol. Rats also infected the company base camps, but living conditions in the camps, although rough, offered less opportunity of contact with contaminated soil, and/or water. Secondary sources may have been wild pigs or numerous dogs.

Method of transmission.—It has long been accepted that contact with mud, slime, and water contaminated by the urine of the rodent or other animal harbouring the infection provides the opportunity for the leptospira to obtain access to the body. It may enter through damaged skin or through intact mucous membrane. Bathing in contaminated water provides other cases. In Malaya, in previous years, patients with leptospirosis have given histories of having bathed in local rivers or old mining pools [11].

Opportunity existed on patrols in jungle: skin abrasions were common: washing and bathing were done in rivers and streams while the standards of water purification were uneven. The importance of contaminated drinking water is stressed particularly when reliance had to be placed on individual methods of purification. The intermittent heavy rains could cause supplies available to patrolling infantry to be contaminated from surrounding areas and so reach individuals or groups. Contaminated drinking water could be the source of those infections which occurred among those whose duties kept them in the base camps with their more elaborate supply systems, the chlorination of which was apt to be irregular and to which rats had comparatively easy access. The origin of the cases in the administrative group is less easy to postulate. The few cases in the Malays could well have come as result of infection acquired during visits to their home kampongs where washing, bathing and drinking water supplies were less than ideal and the domestic economy productive of rats and stray dogs.

Prevention.—Under the conditions imposed by the operations in Malaya, it was impracticable to place a ban on certain areas or particular rivers and streams. The best that could be done was to try and reduce the risk of leptospiræ gaining access to the body. Skin hygiene therefore assumed an added importance while the safety of drinking and washing water supplies and the reduction or discouragement of the rats in company base camps were all stressed. Beyond that, one could do little.

Leptospirosis had become an occupational disease of the jungle patrol.

Discussion.—The occurrence of leptospirosis among the troops in Malaya showed that the disease was widespread in that country. Certain areas were revealed to be of higher endemicity than others. It can be said that the disease could probably be contracted in any State at any time of the year. It was a disease of the jungle patrolling infantryman rather than that of the supporting troops and it could be caused by any one of a large number of leptospiræ.

Mortality was low but it caused considerable incapacity among operational troops.

Series of cases occurred in units which gave the appearance of outbreaks but closer examination generally showed that the cases had occurred among several patrolling groups that had no common epidemiological factor except the general area of the country [12].

No cases could with certainty be ascribed to bathing in a particular river or pool or to using a particular water supply. The origin of the infection lay in the extensive rodent population of the jungle but secondary sources could possibly have been in the wild pig, dogs or buffaloes. The route of the infection was probably the consumption of contaminated water and the contact of abrased skin with contaminated mud, slime and water while on patrol. Of the three main groups the heaviest sufferer was the British soldier. The Malay, recruited in the country, suffered scarcely at all although oddly enough one of the two fatal cases was in a Malay. This suggests some degree of racial immunity. The Malays operated alongside British troops in areas of known high endemicity apparently with impunity. It must be appreciated that the system of National Service resulted in the constant dilution of the British units with "unseasoned" young men. The Malay Infantry on the other hand were a long-service group. Second infections in the same individual were rare so it is conceivable that some immunity can be acquired. The Gurkhas, the third of the large groups, were also long-service soldiers, with continuous service in Malaya for some years. They, although they suffered more than the Malays, did not approach the British in susceptibility.

Of the two small groups, the Fijians, who were diluted with drafts at intervals, seemed to suffer along with the British. The Africans, who were not diluted during their tour, were much less susceptible even though they operated continuously in an area of high endemicity. It seems possible therefore that the longer a unit stayed in Malaya, provided its composition remained stable, its chances of producing cases of leptospirosis were reduced.

In the total of 333 cases, 20 were among officers. With few exceptions these were among the subaltern patrol-leading group and all were British: either in British infantry or serving with Africans or Fijians. No Malay officers (and there were plenty in this group) contracted the illness neither did any Gurkha officers.

Although cultural identifications when carried out showed a large number of different leptospiræ there seemed to be no fixed relationship between the causal leptospiræ and the severity of the illness. Cultural identification could not be done in all the cases but confirmation of the diagnosis by agglutination-lysis, complement fixation or a combination of both was the general rule. It is considered, however, that if it had been possible cultural isolation and identification on a wider scale would have helped to have given a clearer picture of the distribution of the various leptospiræ in Malaya. This might profitably be combined with more extensive serological studies among the indigenous population than has hitherto been possible. The relation of the various rodent hosts and the causal leptospira would also be of interest.

The experience of these two years has put the hazard of leptospirosis in Malaya into focus. From being underdiagnosed in the early stages it then passed through a small peak of overdiagnosis until now the picture is fairly clear. Cultural and serological methods are both essentials for a true picture. The varied clinical picture can cause confusion. This does not only apply to the disease as it is met in Malayan jungle. Admittedly the conditions it found there were optimum for its dispersal and such conditions on such a scale are unlikely to be encountered in ordinary existence. Nevertheless they can be encountered on a small scale from time to time. We must remember that Weil's disease is only one manifestation of the many that are possible in leptospirosis. To some extent we can prevent leptospirosis by adjusting environmental conditions so as to restrict the opportunities for the leptospiræ to reach the body. But conditions of warfare in the Malayan jungle with its ever-present reservoirs of infection and its abundant opportunity did not permit of such adjustments to be fully effective.

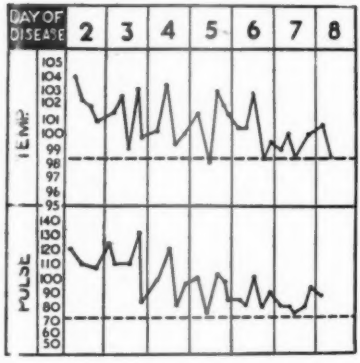
Colonel A. P. Trimble:

Clinical Aspect of Leptospirosis in Malaya

This paper is the result of an analysis of the recorded observations in 236 cases of leptospirosis in Malaya over a period of four years. All were proved either by a rising agglutination titre or by blood culture. The only selection was the ready availability of the notes and the corresponding pathological results.



The disease as we have seen it corresponds in broad outline with the accepted textbook descriptions, i.e. it is a disease without prodromata, of abrupt febrile onset with nausea, vomiting and headache, usually associated early with body and limb pains and tenderness, and injected eyes. Towards the end of the first week in about four-fifths of the cases, renal (70%), hæmorrhagic (18%), hepatic (10%), or meningitic changes (3%) may be expected. Usually more than one occurs, occasionally all four, and the relative severity of each varies within wide limits. In Malaya it was commonly a moderately severe illness with pyrexia lasting a little over a week. It can be the cause of a short three-day fever; or it can be an overwhelming infection that is fatal in a few days. In Malaya dehydration in the early stages was an additional factor.

The signs and symptoms are listed in order of frequency in Table I. The temperature

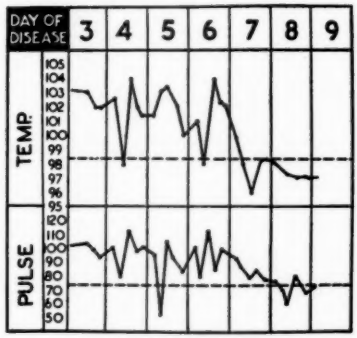


TABLE I.—ANALYSIS OF SYMPTOMS IN 236 CASES OF LEPTOSPIROSIS PROVED BY AGGLUTINATION AND/OR CULTURE ON FLETCHER'S MEDIUM

	%		%		%
Headache	98	Sore throat	25	Tender below L. costal margin	5
Conjunctival injection	80	Glandular enlargement	25	Abnormal C.S.F. found	3
Renal involvement (requiring gastric drip or I.V. glucose)	70 7	Rigors	18	No conjunctival injection or pain or tenderness in body or limbs	3
Vomiting	60	Bleeding	18	Total white count (extremes 4,000 to 30,000) averaged	9,000
Back and body pains	60	Rash present	16	Polymorphonuclear percentage (extremes 20% to 96%) averaged	75
Limb pains	60	Spleen palpable	15		
Muscle tenderness	50	Liver palpable	15		
Injected throat	45	Lumbar puncture performed	11

Neck stiffness	30	Icterus	10		
Cough	30	Tender below R. costal margin	10		
Physical signs in lungs	25				

is usually of the high remittent type. As in scrub typhus, a double rise and fall, perhaps to almost normal in the twenty-four hours, is frequent at some time of the disease. There is not infrequently some regression of symptoms after thirty-six hours but after a further twelve hours, the symptoms increase again and become more intense. The result is often a temperature chart with a distinctive high and very erratic outline and of value in diagnosis (Fig. 1). Rigors may occur. In three-quarters of this series the duration of

A.—Pte. E.

B.—Cpl. B.

FIG. 1A and B.—Two charts of leptospirosis cases to illustrate the high, erratic character of the pyrexia and the occurrence of a double rise and fall in the twenty-four hours.

pyrexia was seven to twelve days. There are three further points about the pyrexia. It not infrequently falls, sometimes to subnormal at the onset of severe renal involvement and may be accompanied here by a severe fall in blood pressure. The mild short secondary rise is well known. Very occasionally a low-grade intermittent pyrexia may follow the acute phase and continue for some weeks. There may be an injected throat (45%), and cough and signs in the chest (30 and 25%), with consolidation at the bases in severe cases. Although glandular enlargement was noted in 25%, the enlargement is very rarely prominent as is so frequently the case in scrub typhus. Although icterus occurred in only 10%, minor abnormalities in liver function tests were fairly common as occurs in many fevers.

Urinary changes.—In 30% of cases there were no urinary changes throughout or only an occasional trace of febrile albuminuria. Such absence of renal involvement is not confined to mild or moderately ill cases. For instance one severely ill patient with both meningitis and hæmatemesis showed no renal involvement throughout. Urinary changes are often delayed. However, even in patients where there has only been moderate urinary involvement there is often some impairment of dilution and concentration for some weeks. So far no case has shown persisting impairment for longer than three months. Warning of the onset of severe oliguria is always given by a study of the daily intake and output chart. In the early stages diminished urinary output and perhaps some rise in the blood urea were more often due to dehydration.

Meningitis.—The incidence of meningitis was only 3%. It was suspected in a further 8% but with normal findings on lumbar puncture. This does not support the contention that an appreciable number of cases have C.S.F. changes without meningeal signs. The fluid showed a moderate increase of cells (maximum 400), mainly lymphocytes, and a moderate increase of protein with low normal sugar levels.

Skin rashes.—There were macular or erythematous skin rashes in about one-fifth of the cases. They appeared on the chest and upper arms from day 2 to day 5. The face may be darkly suffused in the early stages. No hæmorrhagic herpes was noted but herpes labialis is uncommon in Malaya. One further rash occurred, mainly from one regiment during an outbreak. It consisted of macules very similar to rose spots appearing about the seventh day, first about the upper abdomen and spreading to the rest of the trunk and occasionally the limbs. It was associated with late urinary changes or none at all and sometimes an enlarged spleen.

Complications and relapses were few. The main complications were conjunctivitis and iritis. Others were thrombophlebitis, pyelitis and anæmia. Relapses were mild but resembled the original attack. Only two cases of second attacks were proved although the majority were exposed to further risks of infection.

Differential diagnosis.—In the first two days it is often quite impossible to diagnose leptospirosis clinically. At the end of a week it is possible to be correct in about 90% of cases. Points to remember in a typical moderate case are the rapid onset of a high erratic fever with severe headache, pains and vomiting. The eyes are injected, there may be subconjunctival hæmorrhages, and the face is often darkly suffused. The patient tends to lie on his back, immobile because of pain and prostration but he is mentally alert and the picture contrasts markedly with the typhoid state. Signs of involvement of other systems should be watched for, particularly daily examination of the urine. In Malaya, malaria and scrub typhus were the two most frequent difficulties. The prominence of nausea, vomiting and pains is suggestive but a tender spleen is relatively uncommon. On occasion the distinction is anything but clear. Scrub typhus is a very real difficulty and there are a number of cases where it is impossible to differentiate on clinical grounds. Enlarged and tender glands are much more frequent in scrub typhus. It should be noted that the initial OXK titre in the Wilson-Weil-Felix reaction can be high in leptospirosis, but it subsequently falls. Chloromycetin may be used diagnostically. Other difficulties are atypical dengue, the undifferentiated P.U.O.(S.T.) of the tropics, pyelitis and infective hepatitis with hepato-renal syndrome. A polymorphonuclear leucocytosis is almost constant in leptospirosis, and this may help the diagnosis.

Relation of sero-types to severity and symptoms.—I was interested to see if this series supported the claim that different sero-types produced clinically different syndromes (Table II). The overall picture is that leptospirosis most commonly produces a moderately severe illness (the average time off duty was four weeks). Less frequently it produces either a severe or a mild illness in almost equal proportions. None of the groups is markedly different from its fellow, taking chance into account. Certainly icterohæmorrhagiæ, the classically severe sero-type, does not stand out as such. With regard to symptoms, renal involvement is roughly in the same proportion throughout, and analysis of its severity was also proportional. The same observation applies to the frequency of

Unidentified or anomalous ..	71	12	53	6	50	9	13	5	1
Total	236	34	161	41	167	21	41	37	6

Unidentified or anomalous = either culture positive but identification of organism not proceeded with or an equal rise of agglutination titres in more than one sero-type.

hæmorrhagic signs. Icterus did not occur in any of the so-called non-icteric strains, but neither icterus nor hæmorrhagic signs were particularly frequent in icterohæmorrhagiæ. In any case icterus has on occasion been reported in some of the non-icteric types, e.g. canicola and grippotyphosa. Canicola is reputed to cause meningitis frequently. There was no occurrence in our 15 cases. But this is not to claim that there is no correlation. For instance the rose-spot type of rash mentioned before appeared to be associated with either *L. icterohæmorrhagiæ*, *L. canicola* or (more frequently) that anomalous group which showed the serological features of both. The analysis does not support any very close correlation with either severity or individual symptoms.

Summary.—I would suggest that in the past there has been too great a tendency to categorize this disease into a number of clear-cut clinical types often allegedly associated with specific sero-types. It is a disease of extreme variability in severity and of a wide symptomatology, the clinical types overlap in a multitude of ways and the disease is better described as a whole. Study of van Thiel's monograph supports this contention.

Fatal cases.—It may be of interest to describe 8 fatal cases diagnosed as leptospirosis. Although only one was pathologically proved by culture, the diagnosis in the others was clinically satisfactory. All were jaundiced but only 4 heavily so. In nearly all there was a marked hæmorrhagic tendency. 3 patients (one of whom was proved culturally) appeared to die of overwhelming septicæmia on days 4, 5 and 6 respectively. Post-mortem revealed a widespread hæmorrhagic pneumonia with only minor changes in liver and kidneys. Two cases dying on days 7 and 9 were considered to die of liver failure, being deeply jaundiced with reasonable urinary output. Restlessness, delirum and finally coma occurred. The 3 other patients appeared to die of renal failure on days 10, 11, and 14. There would thus appear to be three distinct forms of death—septicæmic, hepatic and renal.

Treatment is initially concerned with the correction of dehydration and the relief of pain and nausea. Pethedine is a most valuable drug. Daily intake and output charts give warning of impending renal failure which can usually be treated adequately by the Borst and Bull regime. It is important to distinguish between the oliguria due to uncorrected dehydration and that due to the disease. If gastric drip cannot be tolerated, or hepatic failure supervenes, inferior vena caval transfusion with 40% glucose should be carried out. The restlessness of hepatic failure will need paraldehyde. Meningitic symptoms are quickly relieved by lumbar puncture. I have no doubt that it is the modern treatment of dehydration and of renal failure that has produced the very low mortality rate (under 2%) in the Army in Malaya. There has been sharp difference of opinion over the value of antibiotics.

Smadel was unconvinced that any of the current antibiotics was effective but favourable claims for penicillin have been made in this country. I have emphasized the great variability in severity and therefore no true assessment can be made except in carefully controlled and reasonably large series. Such assessment must be made on the total symptomatology, and not, for instance, on duration of pyrexia alone. Such a series was reported by Fairburn and Semple and failed to show marked improvement with either penicillin or Chloromycetin. Oral Aureomycin is too irritating. A controlled series with terramycin is at present being carried out. My own opinion is that there is some advantage if antibiotics are given very early in the disease but it is extremely difficult to admit, diagnose and start specific treatment of cases of leptospirosis within forty-eight hours of onset without haphazardly treating a number of quite unrelated diseases. Certainly we have as yet no true specific therapy such as we have for typhoid fever and scrub typhus.

Finally, it has been alleged that leptospirosis in Malaya is one of the milder variants. This analysis does not support that claim (*see* Table II). The number of mild cases is more probably due to the exceptional hospital and laboratory facilities available. There are a large number of sero-types present in Malaya and here they were acting on a completely non-immune community. It is therefore reasonable to suppose that the disease as we see it there is a true reflection of the natural history.

DISCUSSION ON REHABILITATION IN THE ROYAL AIR FORCE

Sir Reginald Watson-Jones:

In former years immobilization of fractures was accompanied by such grave disuse change, with stiffness of joints and wasting of muscles, that Lucas-Championnière went to the length of treating fractures without any immobilization at all. Even until recent years some surgeons have been so afraid of the effects of immobility that they have been ready to discard the use of any form of splints or plaster. The fact is, of course, that a fractured bone or injured joint can be immobilized quite safely without danger of permanent stiffness or muscle wasting provided that throughout the period of immobility the patient is instructed in exercises of the distal joints and static contraction of the muscles in the immobilized area. This applies whether it is a fractured leg in an above-knee plaster, a fractured femur in a Thomas's splint, a fractured spine in a plaster jacket, a fractured wrist in a below-elbow plaster, or a fractured elbow or humerus in an above-elbow plaster. The essential treatment, apart from reduction of the displacement of bones, is to teach the patient active exercises and to make certain that he carries them out regularly at hourly intervals throughout the day for about five minutes each time. It is equally important when splints or plasters have been discarded to teach active exercises by which to regain mobility of joints, always encouraging, cajoling, and persuading the patient to do them hourly throughout every day until functional recovery is complete.

During the First World War Sir Robert Jones planned remedial workshops for this stage of rehabilitation. The centre at Roehampton deservedly gained wide repute. The demands of war have always stimulated the advance of medicine and surgery: as for example the development of nursing under the direction of Florence Nightingale in the Crimean War; the control of disease and treatment of wounds by Ambroïse Paré; the development of antisepsis and asepsis by Pasteur and Lister; the development of antibiotics by Fleming and Florey; the progress of anæsthesia in Edinburgh and Boston; and advancement of the treatment of bone injuries by Hugh Owen Thomas, Robert Jones, and many of their disciples.

Early in the Second World War the importance of gaining complete and rapid recovery from the injuries sustained by pilots, air crews, and ground staff of the Royal Air Force was so great that early active exercises in the hospital wards by rehabilitation orderlies, and follow-up treatment with gymnasia, recreation grounds, and swimming pools in special rehabilitation centres was soon established. It was my opportunity and great privilege, with the enthusiasm of the Director-General of the medical services and the Consultants in Physical Medicine of the Royal Air Force to establish these centres. Fortunately the lesson was not forgotten immediately after the conclusion of the recent great war, and the Royal Air Force medical services still have most excellent rehabilitation centres—the magnificent centre at Headley Court being provided entirely by voluntary subscription. This important development in the management of patients with severe, serious, and often multiple fractures—including for example ten, twenty, or thirty fractures sustained by one pilot—was soon emulated by the Army, the Royal Navy, the U.S. Army, the Australian Forces and the Canadian Forces, and the impetus thus gained has been sustained.

It must be emphasized that the principle of rehabilitation is to encourage and persuade the patient to cure himself. This principle was declared nearly two thousand years ago by Galen who said: "He cures most in whom most are confident"; and even earlier by Plato who said: "This is the greatest error in the treatment of sickness, that there are physicians for the body and physicians for the soul, and yet the two are one and indivisible." The principle of rehabilitation, whether in the earlier stages in hospital wards or the later treatment in special rehabilitation centres, is to encourage active exercises with no passive measures of stretching, forcing, and manipulating, and at the same time to let the patient understand his disability, regain confidence and be inspired, always making sure that fears and anxieties are dispelled, and that social problems are solved. Physical exercise alone is not rehabilitation; psychological and social treatment is just as important as active physical treatment.

Dr. Basil Kiernander:

An extremely happy relationship has developed between the specialties of orthopædic surgery and physical medicine and has enabled the organization to work very efficiently in an atmosphere of unity. This was largely due to the personality of the consultants in Ortho-

pædics, Sir Reginald Watson-Jones and Mr. H. Osmond-Clarke on the one hand, and of the consultants in Physical Medicine, Sir Morton Smart and Dr. C. B. Heald, on the other. The R.A.F. was fortunate in having so many pioneer Medical Officers employed in the specialty of rehabilitation and physical medicine. In this connexion I would comment on the liaison in the R.A.F. between the physical fitness officers and the physical medicine specialists, by which they co-operate not only in the training and provision of suitably qualified physical training instructors in rehabilitation centres and hospitals, but also in the preventive field in which I am particularly interested.

In addition to staffing the residential rehabilitation centres, the physical medicine specialists of the R.A.F. have to supervise the physical medicine departments of R.A.F. hospitals as well as that of the Central Medical Establishment in London. The field in the rehabilitation centres is still largely orthopædic, although other types of cases are being encouraged, e.g. up to 5% psychiatric. At the physical medicine departments there is a cross-section of all types of disorders—medical, surgical, gynæcological and psychiatric—and this is comparable with the experience in a civilian hospital, except that the majority of patients are in the younger age groups. In addition to Service personnel the wives and families of regular members of the R.A.F. are looked after medically, and this introduces a broader sphere of clinical experience than would be possible otherwise. Ideally the rehabilitation centres should eventually be situated within easy reach of the hospitals they serve, as while the atmosphere will then be the correct one of recovery the patients will be capable of transfer there from hospital at an earlier date than at present, when a long distance may have to be travelled. Hence, in addition to speeding recovery and freeing the more expensive hospital bed, it will enable the clinical staff of the hospital to visit the patients in the rehabilitation centres and assess their progress.

To-day the residential rehabilitation centres in the R.A.F. are staffed medically by specialists and trainee-specialists in physical medicine under the administrative control of a medical commanding officer. These officers have full clinical control of the patients during their stay in the centres. They also keep in close touch with the clinicians referring them. They supervise both the physical and mental rehabilitation of the patients, and where necessary vocational training and resettlement in civilian life. Regular visits are made by the R.A.F. orthopædic and other specialists to review their cases, and occasional visits are made as required by Mr. Osmond-Clarke, the Consultant in Orthopædics, and myself.

The importance of early treatment for those patients suitable for admission to the residential rehabilitation centres has been stressed by Sir Reginald Watson-Jones as a method of cutting down periods off duty after hospitalization and reducing sick leave, from which the patients so often return no better. There are an even larger number of patients who have minor disabilities which do not necessitate admission to the residential rehabilitation centres but who can be kept on duty and helped considerably in their return to normality by correct physiotherapy based on active exercises as out-patients, these treatments being carried out strictly by appointment to prevent wastage of man-power time.

The physical medicine department of the R.A.F. Central Medical Establishment offers an example of the need for this type of department.

It was established in 1942, in the first instance primarily for the treatment of minor injuries and postural defects of the several thousand air crew cadets at that time stationed in London, but shortly afterwards it expanded to provide a complete diagnostic and therapeutic physical medicine centre for out-patients stationed in London or within easy reach thereof. By the early summer of 1944 this department had so expanded that a large house in Regent's Park was converted to meet its needs. At that time it was in my charge with the help of the late Sir Morton Smart as Honorary Consultant in Physical Medicine, and in addition to the administrative staff we had ten physiotherapists and an X-ray Department with its own radiographer. This department was able to deal with some 30 new patients a day referred for an opinion, and on the therapeutic side of carrying out treatment for some 7,000 patients per annum. The department suffered repeated damage from enemy action but the work never stopped, and morale was boosted by visits from Their Majesties the King and Queen and other members of the Royal Family during this period. Many of the acute minor disabilities of the locomotor system were dealt with here and the department, although smaller to deal with the needs of the peacetime R.A.F., still continues as a diagnostic and therapeutic centre in the Central Medical Establishment to-day.

A number of interesting surveys and pieces of original research have been done in this department, including on the diagnostic side the use of the first electromyograph employed in the R.A.F.; and a study of various methods of dealing with minor injuries was made, varying from the wartime use of ethyl chloride sprays to the local injection of hydrocortisone at a later date, followed in both cases by early mobilization. A wide variety of pathological conditions were dealt with, including a number of peripheral nerve lesions produced as the result of enemy action, injury from air or other accidents. It is interesting that the first group of patients with poliomyelitis in minor form following serum injections was met with at this Centre during the war. Since the war other research projects have continued and a

the present time, and indeed for the last seven years, a survey of all the cases of facial palsy in the R.A.F. has been studied with the help of the E.N.T. and neurological specialists.

In the post-war period the training of physical medicine specialists and physiotherapists has continued. The R.A.F. is a recognized training centre for the Diploma in Physical Medicine of the Royal College of Surgeons and Royal College of Physicians, the training being provided at the rehabilitation centres and the physical medicine department of the Central Medical Establishment. Where possible, the trainee specialists are also given experience at outside teaching hospitals. Sixteen out of the ninety-five holders of the D.Phys.Med. have received their basic experience and training in the R.A.F., and of these a number have obtained consultant posts in civilian life while a basic core of physical medicine specialists is maintained in the regular R.A.F. Medical Service. The training has proved of such value that the R.C.A.F. have now sent over two regular medical officers for two years' training in this subject.

The R.A.F. now has a physiotherapy training school recognized by the Chartered Society of Physiotherapists for their diploma. The new school was opened last month at R.A.F. Hospital, Halton, and the Medical Rehabilitation Centre at Chessington, with opportunities of obtaining additional experience in appropriate civilian hospitals. In the near future a training school for remedial gymnasts is being opened in the R.A.F. also.

In addition to their work in these various spheres, the medical officers engaged in the specialty are encouraged to carry out research and to take an active part in the appropriate civilian specialist organizations such as this Section and the British Association of Physical Medicine, and to give their services to civilian committees, including working parties of the Ministry of Health and committees set up by the Medical Research Council.

Squadron Leader P. J. R. Nichols:

The R.A.F. Rehabilitation Units at Collaton Cross in Devon and Chessington in Surrey have been functioning continuously since 1946, and up to December 1955 have treated over 26,000 patients, and it is upon the results of treatment at Chessington and Collaton Cross between 1952 and 1955 that this paper is based.

Fractures of the shaft of the tibia.—A total of 353 cases have been studied; 249 patients were treated by closed reduction, including 33 with compound fractures. The 104 patients treated with open reduction included those with internal immobilization with Küntscher nails, screws, plates and bone grafts. The time for clinical union in this series is directly comparable to that recorded by Watson-Jones and Coltart in 1943 (Tables I and II).

TABLE I.—TIME FOR CLINICAL UNION FOR FRACTURES OF SHAFT OF TIBIA AND FIBULA

Weeks for union	Present series	Watson-Jones and Coltart
Under 12	88 (22·1%)	99 (23·7%)
12–24	192 (54·4%)	224 (53·7%)
Over 24	73 (23·5%)	94 (22·6%)

TABLE II.—RESULTS OF REHABILITATION AFTER FRACTURES OF SHAFT OF TIBIA AND FIBULA

	No. of patients	Returned to duty	Regaining "Good" ankle range	Regaining "Good" knee range	Average Total Disability period
Closed Reduction					
Simple fractures ..	216	95%	95%	99%	25 weeks
Compound fractures	33	91%	99·5%	100%	30 weeks
Open Reduction ..	104	92%	97%	96%	35 weeks
Total	353	94%	95·75%	98·3%	28 weeks

Factors affecting the rehabilitation time.—The period between the clinical union of the fracture and return to duty has been termed "rehabilitation time" irrespective of whether the time was spent wholly or only partly at a rehabilitation unit.

214 patients were admitted at least four weeks before clinical union of the fracture of the tibia; the average rehabilitation time was eight weeks, whereas the average rehabilitation time for the 91 patients admitted after clinical union was twelve and a half weeks. The rehabilitation time is very variable and depends on many factors, anatomical, temperamental, and upon the duty for which the patient must be prepared. However, there are three clear trends:

(*a*) The slower the rate of union, the slightly longer the period of rehabilitation required;

(*b*) Open reduction prolongs rehabilitation time.

(*c*) The earlier the transfer of patients to the rehabilitation unit before clinical union, the shorter the "rehabilitation time" (Table III).

TABLE III.—EFFECT OF TRANSFER TO M.R.U. BEFORE OR AFTER CLINICAL UNION (CASES TREATED BY TRACTION EXCLUDED) ON TIME TAKEN FOR REHABILITATION

	No. of patients	Average "rehabilitation time" in days
Closed Reduction		
Simple Fractures		
Admitted before clinical union	134	43
Admitted after clinical union	62	78
Compound Fractures		
Admitted before clinical union	24	67
Admitted after clinical union	7	106
Open Reduction (plates or screws only)		
Admitted before clinical union	56	66
Admitted after clinical union	22	114
All Cases		
Admitted before clinical union	214	58
Admitted after clinical union	91	88
Total	305	67

Fractures of the shaft of the femur.—Fractures of the femur present greater individual problems in treatment and are thus more difficult to analyse in this type of survey (even when the study is confined to fractures of the shaft), as the management of these patients differs much from surgeon to surgeon and from case to case.

80% of our patients with fractures of the shaft of the femur returned to duty, and 80% of these patients regained 90 degrees knee bend or more (Table IV).

TABLE IV.—COMPARISON OF RESULTS OF REHABILITATION AFTER FRACTURES OF THE SHAFT OF THE FEMUR

Type of treatment	No. of patients	No. returned to duty	No. regaining 90 degrees or more flexion of knee	Average time of total disability from injury or from operation
Delayed intramedullary nailing ..	16	13 (81%)	13 (81%)	277 days
Non-skeletal traction	25	18 (72%)	17 (68%)	261 ,,
Open reduction and plating	11	7 (64%)	8 (72%)	258 ,,
Skeletal traction	17	16 (95%)	16 (95%)	253 ,,
Immediate intramedullary nailing ..	24	20 (84%)	23 (96%)	177 ,,
Total	93	74 (79·5%)	77 (83%)	240 days

Although there are so many more variables than in the case of fracture of the tibial shaft, a simple analysis does show a trend indicating that early transfer to rehabilitation units tends to shorten the rehabilitation time (*see* Table VII).

Fractures of the head of the radius.—Fractures of the head of the radius constitute 5% of all fractures (Murray, 1940). Most cases are treated conservatively with two or three weeks' immobilization followed by graduated mobilization. Comminuted fractures and those with marked displacement are frequently treated by excision of head or of the fragment.

53 cases from Collaton Cross and Chessington are available for detailed analysis in two groups: (*a*) those patients with undisplaced fractures treated conservatively; (*b*) those treated by total excision (Table V).

TABLE V.—COMPARISON OF RESULTS OF REHABILITATION AFTER FRACTURE OF HEAD OF RADIUS

Treatment	No. of cases	Average rehab. time in days	Average total disability period in days	No. gaining full extension	No. gaining full flexion	No. gaining full pronation	No. gaining full supination
Conservative	27	31	57	17 (71%)	21 (77·5%)	24 (89%)	26 (96·5%)
Total excision of head	26	63	69	11 (47·5%)	18 (69%)	20 (76·5%)	15 (51·5%)

Our results are compared with figures calculated from the review by Murray (1940) of 459 cases with an average of two and a half years' follow-up. In the case of closed reduction the present series gives immediate results as good as those of Murray's at follow-up, and in the case of total excision of the head the results are better and with a shorter disability period (Table VI).

TABLE VI.—COMPARISON OF PRESENT SERIES WITH RESULTS CALCULATED FROM MURRAY (1940)

Treatment	% of patients obtaining full movements or with less than 10 degrees of limitation		Average disability period (in weeks)	
	Present series	Murray's series	Present series	Murray's series
Conservative	80%	82%	8	5½
Total excision of head ..	70%	44%	10	18

More detailed analysis emphasizes once again the value of early transfer to the rehabilitation unit.

SUMMARY AND CONCLUSIONS

This survey of three disabilities treated at Royal Air Force medical rehabilitation units has, in effect, been a study of the rehabilitation of three joints, and three completely different sets of circumstances and problems of rehabilitation.

Table VII shows the saving of time by early transfer to the full-time Medical Rehabilitation Units in the three disabilities under discussion.

TABLE VII.—SAVING OF TIME IN THE TOTAL DISABILITY PERIOD BY EARLY TRANSFER OF PATIENTS TO REHABILITATION UNITS

Disability	No. of patients	Average total disability period (days) from injury or operation	Average time saved by early transfer (days)	% of total disability period saved by early transfer
Fractured Shaft of Tibia				
Closed reduction (simple fractures)	196	176	35	20%
Closed reduction (compound fractures)	31	212	39	18%
Open reduction	78	223	48	22%
Fractured Shaft of Femur				
Traction	42	258	25	10%
Intramedullary nailing ..	40	203	32	16%
Fractured Head of Radius				
Closed reduction	24	53	23	43%
Total excision	26	69	17	25%

It is most important not to become too obsessed by speed of recovery and the times involved, for, as Holdsworth (1942) stated, as quoted by Watson-Jones and Coltart (1943), "The test of success in the treatment of a fracture is the quality of end-result rather than the time taken in achieving the end-result".

In our organization the determining factor in the disposal of the patient is his functional capability. Within certain limits patients are retained until optimum recovery has been made. Thus variations in treatment are reflected in the time taken to gain specified functional results rather than in variations in end-results, and thus comparisons must be mainly related to the time factor.

What are the alternatives to full-time rehabilitation?

Patients could be retained in hospital; economically a poor solution for the overheads of hospitals are considerably greater than those of rehabilitation units. The patients may be sent on prolonged sick leave to be cosseted at home and allow their muscles to waste and joints to stiffen, to be treated like invalids and lose their morale. Or thirdly they may be given out-patient treatment; but there is no comparison between two or three sessions a week in a hospital out-patient department with the five-hours-a-day programme of residential rehabilitation in an atmosphere of recovery.

We believe that full-time rehabilitation gives results which are superior subjectively and objectively to those obtained by any of the alternatives, and therefore should be more widely available.

REFERENCES.—HOLDSWORTH, F. W. (1942) *Lancet*, ii, 10. MURRAY, R. C. (1940) *Brit. J. Surg.*, **28**, 106. WATSON-JONES, R., and COLTART, W. D. (1943) *Brit. J. Surg.*, **30**, 260.

Squadron Leader J. L. Milligan:

At Royal Air Force medical rehabilitation units weekly resettlement clinics are held for patients who are to be invalided. Here their future employment is discussed and where possible a trial of work is undertaken, either on the unit or under the auspices of G.T.C. Waddon. In these ways a patient may see for himself his suitability for the particular work.

A co-ordination visit to the local disablement resettlement officer is then undertaken to ascertain local employment facilities in the desired work. In this way it is possible for a man to go straight into a job of work or a G.T.C. at invaliding.

The measure of success of this scheme may be seen in the results of a follow-up which has been made over the last five years.

257 replies have been received in answer to a standard *pro forma*. The follow-up period after invaliding varies from a few months to four years, the majority are between eighteen months to two years. 196 or 76% thought the clinic had been of help to them, 34 or 13·2% were not helped. 9 did not need the help of the clinic and 18 gave no reply. The above figure of 76% is probably low because it was obvious from some replies that the resettlement clinic was not differentiated from rehabilitation as a whole.

67 or nearly 26% undertook government training courses and a further 16 undertook various types of private training. Only 3 of the government trainees were dissatisfied with the training they received; the complaints were of out-of-date methods or equipment. A more detailed survey of patients who have had government training courses has recently been undertaken. Allowances were agreed to be just about adequate, but many prospective candidates who were married have been put off courses because of the inadequacy of allowances. Most trainees pointed out the necessity of finding out the local prospects in their trade before undergoing a course.

Three trainees did not subsequently take up the trade of their training, but all said that the courses gave them confidence and independence and were consequently valuable experiences. All but one were registered disabled persons and they found no snags in dealing with their employers on this account. The majority stated that they were better off as a result of their training than they were before entering the R.A.F. or before their disability.

211 or 83% had no difficulty in finding a job on leaving the unit or training centre. 33 had some difficulty, mostly the more severely disabled. 9 were not in work because of their disability and only one is in a home for the permanently disabled.

Of the 244 patients in employment, 193 or 76% were in the same employment as on their discharge. The remainder have changed their employment at least once, of these some were of a temporary nature while awaiting a training course.

205 or 81% were happy about their job and its prospects, of the rest 18 had trouble because of a recurrent disability, 11 were not in the work of their choice often because of their disability and 10 gave no reason for their dissatisfaction.

Of their disability, 121 said it remained static, 95 that it was better and 31 that it was worse. In 4 the condition was stated to be variable.

Our main interest lay in the causes for 33 failures, that is to say with those who had difficulty in finding work, with a view to eliminating these in the future. Of the 33, 11 had difficulty because of chronic relapsing disabilities. These still form the hard core of resettlement problems and no complete answer has yet been found. Two patients were in districts where there was little variety of employment, one a severe poliomyelitis of the (R) arm was forced to do labouring, there being no local alternative, and he is now unemployed. The remainder was due to insufficient adjustment to a disability. It is difficult to see how human error can be completely eliminated in these cases, although increased experience helps.

Many patients remarked on the inadequacy of local D.R.O. facilities, especially following the excellent co-operation and the well-informed nature of the disablement resettlement officers who attend the resettlement clinics. This difficulty has been remarked upon with reference to the training for disablement resettlement officers in the Piercy Report. In an earlier report we quoted that employers were anti-disabled and uninformed, but the more recent replies show that this outlook is decreasing. Only one man stated that his employer was unwilling to pay him full wages for full work simply because he was disabled. Equality for the disabled must still occasionally be the cry. It is obvious from some replies that the liaison between doctor, disablement resettlement officer and employer is still not as good as it should be; surely the medical profession should lead the way.

In all cases the mainstay of the resettlement clinic's success must be the thorough understanding of the patient, his disability and his family background, and no one is in a better position to undertake this than the doctor in charge of the patient. This responsibility we try to accept at R.A.F. medical rehabilitation units, and I trust that we shall continue to try to improve our successes from 86% to 100%.

Squadron Leader C. B. Wynn Parry:

The special features of a rehabilitation centre are the ability to give a full day's really intensive treatment in an atmosphere of confidence and optimism. It is an advantage to have patients with similar disabilities working together, particularly if they can up to a point vie with each other in their speed of recovery and draw heart from seeing others with like afflictions progressing well. The severer the injury and degree of complications, the more likely is a better functional result with full-time treatment.

As an example of this I would like to quote the case of a patient who was involved in a motor cycle accident in July 1955, sustaining a fracture of the left femur and a fracture of the left tibia and

fibula. He also sustained a traction lesion of the sciatic nerve. Five months after injury he was transferred from hospital to the centre for full-time rehabilitation. It was decided that he would need amputation below the knee because of the non-union of the tibial fracture and the complete nerve lesion. Electromyography, however, about five months later showed that there were some early regenerative potentials in the calf muscle and also in the anterior tibials. Treatment was intensified involving non-weight-bearing exercises with knee bend and ankle movements, stimulation of the denervated muscles and re-education of the recovering muscles. To-day the regeneration is such that he has good function in the calf muscle and is now beginning to dorsiflex his toes and ankle. He has knee movements of 175–115 degrees. The skin condition is now very good and there is no doubt that he will keep his leg. Apart from the obvious benefit of the rehabilitation centre in allowing intensive treatment, despite inability of the patient to weight-bear, the effect on his morale has been immeasurable. In a centre of this sort he sees other patients similarly afflicted and has such a full day's programme with discussion groups, entertainments, &c., in the evening that he has very little time to be introspective. Despite his severe disability he has become highly independent, which is after all one of the important aims of treatment at these centres. It is doubtful if the patient's physical and mental condition would have been so good had he not been in a residential centre.

Severely handicapped patients with poliomyelitis, disseminated sclerosis, hemiplegia, paraplegia, and other neurological disorders require retraining in walking, climbing stairs, dressing, shaving and other toilet activities, individual and group muscle re-education, functional assessment for work and vocational training.

Such a patient needs the whole range of a rehabilitation centre's facilities—physiotherapy, occupational therapy, hydrotherapy, educational, welfare and retraining. Not only are these manifold aspects of the patient's recovery difficult if not impossible to cater for in a hospital but the day-to-day observation of progress which is so vital to successful rehabilitation and resettlement is out of the question. The atmosphere engendered by a team approach and the detailed attention to myriad small points in treatment and retraining which make so much difference to the patient's life are not easily given except in a special centre.

The facilities of a rehabilitation centre are no better exploited than in the treatment of severe hand injuries, a subject which is somewhat neglected as a whole but is one of obvious importance. Some illustrative cases follow:

Patient F. J. put his right hand through a window while sleepwalking in June 1955 and severed all the structures in front of the wrist.

Eight days later secondary suture of all the tendons and the median and ulnar nerves was performed. One month later he was admitted to the rehabilitation centre. On arrival he presented with a virtually solid wrist held at 30 degrees palmar flexion, no movements in the m.p. joints, a dry scaly completely anæsthetic hand, very œdematous and an unhealed wound. The patient was a motor fitter, this was his right hand and so the best possible function was essential.

One month after starting rehabilitation he had regained 15 degrees wrist movements but the wrist scar was thick and firmly adherent. The arm was held in elevation, in a sling to counteract the œdema for the first month. Active exercises, electrical stimulation, light craft work and four sessions of oil massage to the scar made up a very full day.

At two months after nerve suture, stretching began in earnest.

In our experience the type of stiff wrist and fingers due to severe lesions such as these with gross tendon adherence at the wrist and resulting flexion deformities of the fingers do not improve with simple active exercises and normal use alone, some form of passive therapy is essential. Manipulations are, of course, completely contra-indicated as they produce more damage and deformity than before. Long-continued slow stretch is the treatment of choice for this type of stiffness.

In the early stages, a plaster splint is moulded on to the patient's hand, being applied from just below the elbow to beyond the finger tips on the palmar surface. The splint is applied immediately after maximum passive correction of the deformity and worn during the day when not undergoing treatment and at night. These splints are changed twice a day in the first two to three weeks, then daily, then every other day and eventually once a week, at this stage the splint only being worn at night. The whole aim of this intensive stretch is to retain every degree of increased movement won in the treatment sessions.

After six weeks' treatment there was 45 degrees palmar flexion and 10 degrees dorsiflexion, a full passive range of the i.p. joints when the m.p. joints were flexed but a 70 degree deformity in m.p. extension.

By three months, a full range of wrist movements was restored and there was only a 10 degree flexion deformity of the i.p. joint. The scarring and adherence were almost gone and the hand was looking in good condition. Lively splints were made to prevent deformity and encourage function in the workshops and in normal use (Smythe and Wynn Parry, 1955). The nerves recovered at the rate expected of neurontmesis and a full programme of re-education started. This included two half-hour sessions of individual muscle exercise, and pattern re-education in the physiotherapy department, a wide variety of games and craftwork in the occupational therapy department, such as basketry, leatherwork, and carpentry. Metal work and job re-education came later when sensation and functional recovery allowed. In all, he spent nine months at the Unit and when discharged was able to undertake all the duties of his trade as motor fitter.

On review fifteen months after injury, his sensation was almost completely normal, all muscles

except third and fourth interossei were working well. His grip was 1 lb. less than the other hand and the only things he could not manage with ease were very fine manœuvres such as putting a split pin into a hole, but this was improving all the time.

There are a number of features in this type of case that deserve comment. The gross adherence and stiffness and flexion deformities that inevitably arise in a severe lesion require full-time very carefully graded intensive attention, the recovery of power and fine function necessitates extensive re-education.

Such patients need constant encouragement best afforded by a centre where others with the same disability are being treated. It must be stressed that the best results in our experience demand really detailed and closely supervised therapy. Choice of work activities in the various stages of recovery must be carefully matched against what muscle action is present and sensory hyperæsthesia. It is no good expecting a man to handle a screwdriver if it causes unpleasant hyperæsthesia throughout the hand, as commonly happens in recovering nerve lesions. With very few exceptions these patients never regain good function if sent back to work in the hope that they will rehabilitate themselves. These patients require full-time intensive rehabilitation for months on end.

The second example of a hand injury I would like to give is that of a patient who sustained extensive burns of the hand in an aircraft crash as well as to face, legs and shoulders. Skin grafting was carried out five and twelve days later and he came to the centre 2/12 after the accident. The backs of both hands were covered in thick tough scars, such that there was no flexion in the fingers and 10 degrees palmar flexion only (Fig. 1). A full programme of oil massage several times a day,

FIG. 1.—Maximum range of flexion of fingers two months after burns.

FIG. 2.—Range of flexion after seven months' treatment. → Same case as Fig. 1.

O.T. exercises, active assisted movements was carried out. During the course of treatment he twice returned to hospital for excision of scars and webs with thin split grafts.

9/12 after the accident he had virtually normal hands and was able to return to full duty (Fig. 2).

It has been my purpose to suggest that for a certain type of patient, a full-time intensive regime of treatment in a special centre offers the best opportunity for the best functional results. Whether a day or residential centre is best or fuller use of hospital facilities depends so much on the district, work available, patient's domestic background and many other factors. But the choice is unimportant compared with the principle of the service offered.

It is our opinion that for patients who would materially benefit from such treatment, more centres should be established. Perhaps local industry might make work available to these centres so that patients undergoing rehabilitation might earn by productive work arranged where possible to increase function of the particular limb, on the lines pioneered by Vauxhalls.

There would be immense practical difficulties in such a scheme but as people will continue to suffer from locomotor disorders, ride motor cycles and put their hands through windows it might be worth making a start.

JOINT MEETING No. 1

Section of Orthopædics with Section of Physical Medicine

Chairman—E. STANLEY EVANS, C.B.E., F.R.C.S.
(President of the Section of Orthopædics)

[*October* 18, 1956]

DISCUSSION ON THE PRESENT POSITION OF MANIPULATIVE TREATMENT

Sir Reginald Watson-Jones: It is intended that this discussion should exclude such manipulative treatment as is concerned with the reduction of dislocations and displaced fractures, and that it should be limited to other types of manipulative treatment. There are five groups of cases to be considered: (1) Mobilization by manipulation of joints seriously stiff after injury or prolonged immobilization in plaster; (2) joints with minor strain in which manipulation may be needed for local adhesion formation; (3) osteoarthritic joints in which symptoms may sometimes be relieved by manipulation and stretching of the associated adhesions; (4) manipulations of joints of the spine for adhesions or prolapse of intervertebral discs; (5) minor manipulation which is to be regarded as part of the psychological treatment of a patient with a functional disorder superimposed on minor physical disability.

(1) *Manipulation of seriously stiff joints.*—For at least fifty years it has been known that joints seriously stiff with massive adhesion formation react badly to manipulation under anæsthesia, and still more badly to repeated manipulation day by day. Although it is true that such manipulations stretch or tear adhesions the sero-fibrinous exudate of the manipulation gives rise to still more stiffness. This is shown most clearly when the metacarpo-phalangeal and interphalangeal joints of the fingers are stiff after injuries of the hand and wrist. The greater the force that is applied the greater is the stiffness of the joints. The essential treatment in these cases is the patient's active exercises repeated hourly throughout the day with no more passive aid than by the patient himself and certainly not by forcible stretching by a physiotherapist or forcible manipulation under anæsthesia by a surgeon. Physiotherapists at their meetings always deny that such forcible measures are used, but in fact they are, even up to this very day. Hardly a week goes by without me seeing a patient with stiff fingers whose joints are being made still more stiff by such measures.

The same is quite obviously true of the injured elbow. Ordinarily a supracondylar fracture of the humerus, or fracture of the head of the radius, or even simple traumatic synovitis will always regain a normal range of movement if the joint is left to itself; whereas the joint becomes steadily more stiff if manipulative treatment is used. The recovery of movement is of course slow, and if patients with such injuries are referred to a physical medicine department very few physiotherapists can go on resisting the temptation to push or force the joint. The answer is that no patient with stiff fingers or stiff elbow after injury should be referred to a physical medicine department at all, and that no more should be done than to instruct the patient in his own active ordinary use of the joints.

Exactly the same is true of the shoulder that is stiff after a dislocation of the joint or after peri-arthritis with adhesion formation. Many surgeons are afraid of immobilizing a dislocated shoulder-joint for four weeks, especially in elderly patients, because of their fear of

permanent stiffness; but it is by reason of their fear, and the vigorous manipulative measures they use, that the joints remain stiff. No matter what the age of the patient, a dislocation of the shoulder can be immobilized quite safely with the limb bandaged to the trunk for four weeks provided that thereafter active exercise alone is relied upon. So it is of the shoulder that becomes stiff from peri-arthritis and peri-articular adhesions. I was amazed at the almost universal despair shown at a recent meeting of the British Orthopædic Association as to the prognosis of stiffness of the shoulder from this cause. The fact is that their dismay arose only from the unduly forcible manipulative measures that had been used. If the patient is instructed in the necessary active exercises repeated hourly throughout the day and is seen week by week, or month by month, just to give encouragement, a normal range of movement is regained within about three to six months.

This principle applies also to the knee-joint that is stiff as a result of immobilization in splints or plaster for several months. Many surgeons are unwilling to use the most excellent operation of arthrodesis of the hip, which gives brilliant results, because of their fear of stiffness of the knee; but here again if active exercise is relied upon to the exclusion of forcible manipulation, and the patient is encouraged sufficiently often, an almost normal range of movement is nearly always regained. If the knee-joint is stiff in consequence of a fracture of the shaft of the femur which has necessitated immobilization for some months the danger of forcible manipulation is still greater because the quadriceps muscle has become adherent to the bone at the site of fracture, and if the joint is manipulated there is a considerable danger of fracture of the patella, or avulsion of the ligamentum patellæ, or tearing the insertion of the quadriceps muscle from the patella. Of all the hundreds of stiff fingers, stiff elbows, stiff shoulders and stiff knees that I see after injury or long immobilization I do not manipulate more than two or three a year, and even then only with great caution.

(2) *Manipulation for adhesions after simple strains of the joint.*—Twists of the knee-joint often strain the medial or lateral ligament or the coronary attachment of the menisci, and although the essential treatment is always restoration of muscle control of the joint by static quadriceps exercises there is a small proportion of cases in which pain and local tenderness remain as a result of minor adhesion formation which can be relieved if the joint is gently manipulated under an anæsthetic and the tibia fully rotated on the femur in each direction.

Similarly, after minor sprains of the ankle, adhesions may remain especially on the lateral side between the malleolus and tarsus and recovery is accelerated by a gentle manipulation under anæsthesia. There may be adhesions around the tarsal joints from which recovery can be accelerated by gentle manipulation. When the toe-joints have become somewhat stiff in the clawed position, active exercise is again the basic treatment, but gentle manipulation consisting entirely of traction with flexion of the joints may be beneficial; especially is this true of minor degrees of hallux rigidus. Traction should be applied until a sulcus or dimple of skin is evident at the level of the joint; while the traction is maintained the toe is gently dorsiflexed.

Some years ago Sir Herbert Barker demonstrated to the British Orthopædic Association at St. Thomas's Hospital a series of thirty or forty cases treated by manipulation, and although nearly every knee-joint with torn cartilage, hip-joint with arthritis, shoulder-joint with recurrent dislocation, and very many other of the cases he manipulated under anæsthesia were subsequently operated upon, he did achieve considerable success in patients with hallux rigidus, and also those with tennis elbow in whom the joint was stretched in the direction of cubitus varus with the forearm first supinated and then pronated, the patient's own active exercise being relied upon thereafter.

(3) *Manipulation of osteo-arthritic joints.*—Many surgeons advocate manipulation under anæsthesia of osteo-arthritic joints, but curiously almost all limit such manipulations to osteo-arthritis of the hip-joint. Surely such treatment is entirely wrong. Degenerative arthritis of the hip, which occurs so commonly in middle-aged and elderly patients, is evidence of wear of the joint. The important measure is that the patient should learn to use the joint within the limit of tolerance of activity and not force it beyond that. What good purpose is served by over-driving and over-straining a hip-joint by manipulation rather than encouraging the patient to use the joint with his ordinary activity and recreation within its limit? Forcible manipulation of osteo-arthritic hip-joints never gives more than temporary relief and, indeed, commonly aggravates the degenerative change. The same is true of osteo-arthritis of the intervertebral joints of the spine which need protection from over-use and not force.

(4) *Manipulation of the spine for low back pain and prolapsed intervertebral discs.*—Great success has been claimed by Cyriax and others in the treatment of low back pain by traction-manipulation repeated quite frequently and without any anæsthetic. It is true that if an intervertebral disc is prolapsed a manipulation of this type may replace it with

dramatic success; but it is also true that such manipulation may increase the displacement so that whereas the patient can walk into the department he has virtually to be carried out on a stretcher. In earlier publications such manipulation was said to cure low back pain because it corrected sacro-iliac subluxation; now the same manipulation is acclaimed because it is supposed to correct prolapse of a disc. The fact of the matter is that it is a harmful procedure no matter what the source of the low back pain may be, whether sacro-ileitis, early ankylosing spondylitis, prolapse of a disc or, as in quite a number of cases that I have seen, tumours of the sacrum, tuberculous disease of the sacro-iliac joint or tuberculous disease of the lumbar intervertebral joints. Simple bed-rest and then the protection of a corset achieve far greater success than any type of manipulation.

(5) *Manipulation as an aid to psychological treatment.*—Every patient, no matter how mentally stable and psychologically sound, who has a source of pain develops some degree of psychological reaction by which the pain may be increased especially when miserable, depressed or worried. The common error is to ascribe this to a purely functional disturbance without recognizing the underlying organic disorder. Nevertheless, these functional manifestations are so common, even in the most normal of us, that firm handling, encouragement and reassurance are needed. Sometimes an anæsthetic with gentle manipulation of the affected area assists in the recovery.

There is a centre north of London where apart from insistence on a diet little more than orange juice, a procedure known as "bloodless surgery" goes on. The patient is placed on an operating table and draped with towels; the surgeon scrubs up and dons cap, mask and sterile gloves and then places his hands over the site of pain but never in fact even touches the patient. That is quite probably the best form of manipulative treatment; the more constantly that a physiotherapist can be persuaded to treat a patient without touching, the more certainly will the patient be cured.

Dr. H. A. Burt:

I shall confine my remarks to discussing the value of manipulative treatment in rheumatoid and osteo-arthritis and in the frozen shoulder.

Rheumatoid Arthritis

Two erroneous beliefs about rheumatoid arthritis persist: The first is that rheumatoid arthritis is a disease which "burns itself out" in a matter of a year or two; the second is that it is wrong to manipulate a rheumatoid joint while the disease process in it is active. Some even go so far as to advise against manipulation unless the sedimentation rate is normal.

With regard to the belief that the disease is self-limiting it is admittedly true that there are cases which become inactive within a few months. On the other hand, there are a great many patients in whom activity continues for years and sometimes indefinitely. It is my experience that manipulation may be of the greatest importance for some patients in this long-term group. If manipulation is delayed until the disease is inactive not only is valuable time lost, but the technical difficulties become greater, the procedure is more tedious and painful for the patient, and the results are not so good.

The wrist.—It is very rarely safe or proper to be dogmatic about indications for treatment in any disease but I believe there is one absolute indication for manipulative treatment in rheumatoid arthritis, namely, in the patient whose wrists are becoming fixed in a position of palmar flexion. With the wrist in this position not only is a satisfactory grip impossible, but the likelihood of ulnar deviation of the fingers is very greatly increased. Indeed, I was brought up to believe that a patient who developed a fixed dorsiflexed wrist in the early stages of the disease never developed subsequent ulnar deviation.

A young man developed rheumatoid arthritis in the summer of 1949 and was admitted to University College Hospital in June 1950. At that time both wrists were warm, swollen and flexed and it was not possible to straighten them, let alone put them into a position of dorsiflexion. His sedimentation rate was 25 mm. (Westergren). He was manipulated under anæsthesia in July and again in August 1950, and finally in October 1951. On each occasion the wrists were put into plaster after the manipulation and the patient was ultimately fitted with moulded leather wrist supports. In the X-ray taken in 1955 there is considerable disorganization of both wrist-joints and complete ankylosis of the carpus. He is, nevertheless, able to do light engineering, and his grip is as strong as my own.

It is most unlikely that this satisfactory state of affairs would have come about without manipulation, or if manipulation had been delayed until the disease became inactive.

The knee.—Another indication for manipulative treatment which is almost as important as the last occurs in patients with fixed flexion of the knee which persists or deteriorates in spite of physiotherapy, injections of hydrocortisone or splints.

The technical difficulties of manipulation in such circumstances may be great. With long-standing disease, and particularly in elderly patients, the results are often disappointing. Nevertheless manipulation is usually justifiable, provided that little is done at a time and the manipulation repeated at intervals. Frequently at the first attempt nothing seems to have been achieved but if the procedure is repeated a week later it is often much easier and a significant increase of joint movement is obtained.

The co-operation and willingness of the patient are essential when a number of manipulations are contemplated. This co-operation is only likely to be maintained when anæsthesia is good, plasters, if applied, are comfortable, and post-operative pain properly controlled with analgesics. In fact, with such manipulations, doing only a little at a time, post-operative pain is seldom a serious problem.

I am not convinced from my own experience that injection of hydrocortisone at the time of manipulation is of value; I think it may in fact add to the immediate post-operative pain.

The foot.—It is common for patients with rheumatoid arthritis to complain of pain and discomfort in the feet. If this pain is analysed it will be found in the majority of cases that it does not arise primarily from the arthritis. Rather is it of the same nature as chronic foot strain and arises from the ligaments around the mid-tarsal and less commonly the sub-talar joints of the foot. The importance of mobility in the joints of the foot has frequently been emphasized. It is, as Wiles points out, the key to the problem in certain types of painful feet. "A supple foot", says Wiles (1955) "whatever the habitual posture, seldom causes serious trouble, but a stiff foot, whether it is stiff because of an unresolved sprain, arthritis or contraction of the ligaments, is liable to become painful when subjected to strain." (For a full account of foot strain, Bankart, 1932, should be consulted.)

The only satisfactory method of treating this condition is by manipulation and the results in a large majority of cases are excellent. The results are in fact usually as good as those of manipulative treatment for foot strain due to other causes. It is often unnecessary to use an anæsthetic and satisfactory results follow repeated mild manipulations carried out in the out-patient department. When manipulation of the mid-tarsal and sub-talar joints is performed it is safe to apply a greater force than can be used in the case of other joints. This is in keeping with the belief that here we are dealing with a chronic ligamentous strain rather than an inflammatory condition of the joint.

After manipulation regular physiotherapy is necessary and it is important that passive movements, in particular those NOT under voluntary control, should be given.

Osteo-arthritis

Passing to osteo-arthritis I shall first discuss mobilization of the patella in osteo-arthritis of the knee, and second, the use of traction and distraction in osteo-arthritis of the hip.

The knee.—In osteo-arthritis of the knee, particularly in those cases where there is a superadded traumatic arthritis or peri-arthritis, mobility of the patella is diminished and the peri-articular structures in the infra-patellar region are often extremely tender and sometimes swollen. Gradual progressive manipulation without an anæsthetic, will often mobilize the patella and, in consequence, the range of movement of the knee increases. It is sometimes useful to combine this procedure with injection of the tender peri-articular structures with ½% lignocaine or a mixture of lignocaine and hydrocortisone.

The hip.—In osteo-arthritis of the hip temporary improvement in the mobility of the joint can often be quite painlessly produced without anæsthesia in the following manner. The patient lies supine on the couch and traction is exerted in the long axis of the limb; alternatively momentary traction is applied with the hip held in about 50 degrees of flexion with the knee at a right angle. Such manipulation is a useful adjunct to treatment with sling exercises: it should always be performed whenever lignocaine or hydrocortisone is injected round the joint.

Frozen Shoulder

I shall end with some observations on manipulation in the painful non-arthritic shoulder with limitation of movement—the so-called frozen shoulder. Admittedly this is a controversial subject. It has been stated that manipulation must inflict further damage on periarticular structures, producing increased inflammatory reaction and

pain, and possibly further restriction of movement. It is undeniable that this sequence of events may occur, but it can usually be avoided if movements during manipulation are rigidly restricted to traction combined with rotation.

Forced abduction should never be carried out; this movement aggravates the condition because during its execution there is nipping of the already inflamed bursa, tendons or capsule between the greater tuberosity of the humerus and the under-surface of the acromion.

It is my experience that once the frozen shoulder becomes painless, movements steadily and surely return of their own accord. As a rule, therefore, manipulation of the painless, stiff, shoulder is unnecessary and, incidentally, may bring about return of pain. There are a few occasions when manipulation to improve movement is justifiable, as, for example, in the case of the manual worker where limitation of shoulder movement imposes a definite handicap at work.

The chief indication for manipulative treatment with the frozen shoulder is *persistent* pain. Manipulation should always be considered in cases where pain is increasing in spite of adequate treatment, and especially if nocturnal pain is becoming more severe.

In my experience the injection of hydrocortisone into the shoulder at the same time as the manipulation has not resulted in improvement. There is, however, one situation in which injection of hydrocortisone combined with lignocaine and hyalase is undoubtedly helpful and that is the substance of the pectoralis major, a muscle which is very frequently tender and tight in this condition. I now give this injection as a routine whenever I manipulate a painful shoulder.

WILES, P. (1955) The Essentials of Orthopædics. 2nd ed. London.

Dr. Guy Beauchamp:

The position of manipulation to-day is very much what it has been for the last fifty years. Those who practise it are satisfied with the results, those who will not or cannot manipulate condemn it. It is a fact that with the well-known manipulators in the past, whether they have been bone setters, osteopaths, or medical men, the world has beaten a path to their door. Sir Herbert Barker, Blake of Charterhouse Square, Bennett of Leamington, Nicholas of Cavelaire, Sir Morton Smart, Marlin and Mennell here in London, are names that spring to mind. The manipulator himself finds this a most satisfying work. Results follow with great speed in the majority of cases and are accepted by the patient with great enthusiasm.

Manipulators fall into three groups:

(1) Orthopædic surgeons; (2) Medical orthopædists; (3) Osteopaths and the subsidiary group of chiropractors.

The techniques of these groups differ widely, by reason of the development of their craft. Orthopædic surgery had its ancestry in bone setters. Medical orthopædists developed manipulation against the background of physiotherapy; osteopaths, the first to practise spinal manipulation, derive from the teaching of Dr. Andrew Still, himself a qualified medical practitioner. His teaching was that in manipulation of the spinal and sacro-iliac joints lay the sovereign method of relieving symptoms. It is not necessary to dwell upon the theories, but it is important to recognize that the teaching in good osteopathic colleges is excellent; anatomy and physiology receive as much attention as in medical school, and the hours of patient learning of techniques might well serve as a reminder of the inadequacy of the young doctor to compete in the field of spinal or other manipulation. It is not an art that can be acquired in six easy lessons, nor will it be learned adequately until some parallel system of teaching is adopted. There is decreasing divergence between certain trends in physical medicine and osteopathic teaching. It would be all to the good if the principle that "structure governs function" were accepted. Indeed what argument can be used against this principle?

So much for the manipulators. Now what of the manipulated? I have recently assessed 300 consecutive patients, who had been referred specifically for manipulation, after examination and diagnosis by their own doctors. Some had had other forms of treatment but most had arrived with an established diagnosis and treatment by manipulation had been asked for by the patient or advised by his doctor. We can see therefore the type of case for which manipulative treatment is likely to be sought.

The first interesting point was that with a great number manipulation was chosen as the initial treatment, whereas ten years ago they would have already run the gamut of physio-

therapy. This is a great advance, and it is certain that the teaching and writings of Mennell and Cyriax have been largely responsible for this.

There was a predominance of females over male, 58% female, 42% male, and less than half (151) complained of low back pain, and of these only 43 could be positively diagnosed as intervertebral disc propulsions. These figures do not support the contention that most backache is due to a disc lesion. In this number of disc lesions there was no disproportion between male and female, but in the other groups where backache was due to other causes there were twice as many females as males. Sacro-iliac strain accounted for 59, the females predominating by 10·6% over 6·3% males.

The next largest groups were those complaining of pain in the neck and shoulder girdle. Cervical spondylosis accounted for 66 of these, 10% male and 8% female.

The next largest group in this division was of derangement of the occipito-atlantal and atlanto-axial joints, occurring without spondylosis or other recognizable pathology. These accounted for 18% of the total; 5·4% male and 12·9% female. This group is one of the most fascinating and rewarding in the manipulative field and although it has received scant attention in the past, manipulation is the only satisfactory treatment. The signs and symptoms are characteristic. Limitation of mobility in varying degree, pain referred to occipital, frontal or parietal area, hemicrania, hypertension, tinnitus, giddiness, alteration in the special senses and profound fatigue being the usual manifestations, and occurring in variable degree and combinations. Treatment by manipulation is easy for the patient in the majority of cases; though the technique is tricky a single treatment may suffice and effect an immediate cure. So-called idiopathic hypertension is closely linked with this group and of the 350, 5 patients with hypertension presented themselves for treatment. Some of these had recognizable mechanical disabilities, the correction of which was effective in relieving their hypertension. Where no derangement was found, hypertension was unaltered by treatment.

It is certain that where a subluxation occurs imbalance of muscle action must occur and there then follows a reduction in the blood supply to the malfunctioning tissues. There will also be increasing loss of function and of elasticity. Avascularity may extend far beyond the affected area and be responsible for most of the subjective symptoms of these conditions.

It is my belief that all patients who have manipulative treatment need exercises afterwards. It was the late Sir Morton Smart who said that manipulation without exercises was useless. This I think is a little exaggerated, but it serves to drive home the necessity of such after-treatment. Massage and heat play no part at all in recovery after manipulation; it is for the most part a waste of time and money and often greatly delays recovery.

In none of these 350 patients was any anæsthetic used, nor would it have been particularly safe to manipulate under anæsthesia the occipito-atlantal and atlanto-axial subluxations. The manipulative thrust is made with the patient in the sitting position, the head of the patient is extended and the thrust is an upward and backward screw movement. Considerable force is used through a minute distance and is certainly not to be used without some voluntary positional control. Occasionally and especially in children, where fear or pain are dominant, it may be necessary to use an anæsthetic for upper cervical joint lesions, but the majority of treatments can be made without anæsthesia.

Dr. A. T. Richardson:

Although pain referred from spinal structures is one of the commonest symptoms complained of by patients attending orthopædic and physical medicine departments, it is in only a few that a causative lesion can be demonstrated with any certainty. For the remainder an extraordinary number of diagnoses and treatments have been suggested. Formerly when fibrositis and other terms, implying at the most a non-specific inflammation of various soft tissues, were popular, no more than the application of harmless analgesics and heat seem indicated. In contrast the diagnosis of prolapsed intervertebral disc, which is now frequently applied to any spinal pain of undetermined origin, so frequently in fact that it is rapidly becoming devoid of any pathological implications, suggests a specific mechanical derangement. This has led not only patients but also medical practitioners to enquire about the possibilities of manipulative replacement of "slipped discs". Many of the doctors, to judge from some of the 36 letters which followed an article by Cyriax (1955) are remarkably enthusiastic about this form of treatment.

In theory, manipulation can be effective in relieving pain caused by replaceable displacements and by fibrous adhesions in and around a joint or attached to a normally mobile structure. Unless one of these conditions exists and can be diagnosed and unless it can be ensured that manipulation will have the desired effect without producing any harmful results, it is not indicated.

These criteria would seem to be satisfied in only a limited number of the patients afflicted with pain of spinal origin who attend hospital as out-patients. Thus, while the diagnosis of vertebral disease can be firmly made on the basis of the typical clinical and radiological appearances, there are no displacements or adhesions to manipulate, except, perhaps, following fractures. As regards painful disease of the intervertebral joints, while ankylosing spondylitis has typical clinical and radiological signs, degenerative joint disease of the spine generally has no characteristic clinical signs and is such a common radiological finding in the older age group that it is difficult to relate it to pain in any particular case. Exceptions to this are, first, in the uncommon event of degenerative disease of the cervical neurocentral and apophysial joints occurring as part of a primary generalized osteo-arthritis. In this event, as is the case with osteo-arthritis of the peripheral joints, manipulation is not often called for except when mobilizing exercises have failed to restore mobility. The second occasion when pain can be related to degenerative changes is when it is associated with symptoms of pressure on nerve roots or spinal cord. Here manipulation is fraught with risk by virtue of the fact there is no way of protecting the already damaged spinal cord or nerve roots from increased damage by manipulation.

The remainder of cases of spinal pain are made up of a group which has little variety in symptoms, no specific signs, equivocal X-rays and negligible pathology and which, therefore, as I have said, attracts many diagnostic labels. However, within this group the clinical entity of acute lumbago, acute cervical pain and perhaps acute dorsal spinal pain are recognized. The essential features are pain of acute onset, often recurrent, which is produced by movement of the relevant part of the spine which is held rigidly. There are no symptoms or signs of cord or nerve root pressure and X-rays show no more than loss of the spinal curve or perhaps the usual degenerative changes if the patient is in the older age group.

While the exact nature of the lesion or lesions causing these syndromes is a matter of controversy, there is an increasing body of opinion which associates them with mechanical abnormalities of the intervertebral joints. Particularly in favour of this concept is the occasional occurrence of pain of fulminating onset and equally sudden remission, which suggests a mechanical derangement and not an inflammatory state. As to the type of articular derangement, some stress the importance of the apophysial joints, and infer nipped synovial fringes, loose bodies or subluxation in these joints (Crisp, 1952), but to most the intervertebral disc is the root of all evil. The theory that intervertebral disc lesions are the common cause of acute spinal pain of this type is largely based on the fact that in some cases pain eventually radiates in root distribution, is accompanied by signs of nerve involvement and so presents the accepted clinical picture of intervertebral disc degeneration. If, in fact, the lesion of acute spinal pain of this type is a mechanical derangement of the apophysial joints, manipulation would seem the only form of direct attack on the lesion and should be harmless. If, in fact, the underlying lesion is disc degeneration the place of manipulation is more debatable. However, whether it be considered that the pain is due to disc prolapse with bulging of the posterior ligament and perhaps dural pressure (Cyriax, 1945) or displacement and impaction of a nuclear sequestrum (Armstrong, 1952), if it is believed that these can be replaced by manipulation without the risk of damage to nerve tissues, the treatment would seem justified.

The ætiology of chronic spinal pain in which no definite and significant lesion can be demonstrated is even more speculative. Some cases derive from trauma, others from recurrent acute attacks, and in yet others postural abnormalities or degenerative articular changes seem to be responsible. Psychological factors are constantly present and sometimes dominate the clinical picture. It follows that the theoretical indications for manipulation are even more difficult to define, but it would seem reasonable that where loss of spinal movements has occurred and has not been restored by mobilizing exercises manipulation may be indicated, the object being to stretch or break any fibrous adhesions or capsular contractions contributing to the immobility and pain, and not for psychological reasons!

Whatever the theoretical considerations for manipulation, widespread acceptance of this form of treatment must depend upon results. It has been argued that manipulation of the spine is so often carried out by lay practitioners that some patients must benefit in some way and indeed we have all seen patients, even doctors, who appear to be reliable witnesses and who state their symptoms have been relieved by manipulation. However, it is equally common to meet patients who trace the onset of their symptoms to manipulation or who state they have had more pain, often of root distribution and accompanied by paræsthesiæ, etc., following this form of treatment. Reference to the literature shows that opinions on spinal manipulation range from that of Cyriax (1955) who states that unilateral scapular aching associated with pain on moving the neck can be relieved in 99% of cases by one or two sessions of manipulation and that "in backache manipulative treatment, without anæsthetic, is usually successful" to Charnley (1955) who in discussing acute lumbago and sciatica does not recommend manipulation at all, although he states "the sequestrum type of lumbago is the one which has sometimes been relieved by manipulation". The more

general view is perhaps that expressed by Coltart and Osmond-Clarke (1955) who state "we have found that quite a few cases of acute low back pain with fixation (lumbago) can be relieved immediately by single manipulation without anæsthesia if seen early enough" and similarly Wiles (1955) discussing acute lumbago states "manipulation is a simple method of treatment and relieves many acute attacks almost at once" and discussing acute stiff neck says "an attack can usually be terminated quickly by manipulation".

Unfortunately only one controlled investigation into the place of manipulation in spinal pain, in fact in backache, has been published, by Coyer and Curwen (1955). They treated alternate cases either by manipulation or by bed-rest with a lumbar pillow and analgesics, rejecting only those showing root pain, signs of nerve root pressure, or X-ray changes other than congenital abnormalities or degenerative changes. The design of the experiment has been criticized and doubt over the final result in 16 patients of the control group of 76 has reduced the statistical significance of their figures, nevertheless, three conclusions would seem to be justified from their results. First, that with the bed-rest regime this type of backache remits within a few weeks. Thus, they were able to discharge 50% of their control cases pain free at the end of one week, 60% at the end of three weeks and at six weeks only 28% had symptoms. Second, they recorded no adverse effects following manipulation of 76 patients although this manipulation was carried out in some instances by physiotherapy students. Third, that while the results of manipulation were better than those produced by bed-rest alone, their results do not support the claim of the uncritical enthusiasts that manipulation is the panacea for all backache. Finally I must emphasize the necessity for X-rays before manipulation particularly in view of the amount of this treatment being carried out by general practitioners who have no access to X-ray facilities. Occasionally serious lesions of the spine present as acute neck pain or lumbago without neurological involvement; the manipulation of them can be disastrous.

I conclude, therefore, that on theoretical grounds and from published results for what they are worth, the conditions for the effective and harmless use of spinal manipulation are likely to exist in the early stages of acute spinal pain in which no neurological signs and symptoms are present and X-ray shows no significant disease. There may also be a case for manipulation of the chronically painful spine with immobility in which no specific lesion can be found and where mobilizing exercises have failed. However, the need for an adequate investigation into this form of treatment is obvious and until this has been done I feel the creation of enthusiasm for this form of treatment in the ranks of physiotherapists is to be deprecated. I have no doubt that analgesics, bed-rest, corset or neck collar and various forms of physiotherapy remain the mainstay of treatment of spinal pain.

The Incidence of Primary Hepatic Carcinoma in Cirrhosis

By R. G. F. PARKER, M.D.

Bernhard Baron Institute of Pathology, London Hospital

IT will be argued in this communication that in England malignant change complicates cirrhosis oftener than is generally appreciated. The last detailed report on the subject from this country was that of Stewart (1931), who found primary hepatic carcinoma in 3·41% of all cirrhotics (or in 7·3% if slighter cases were excluded). Since then there have been only passing references to suggest that the incidence in England, and in Europe generally, may in fact be considerably greater than this.

It is important to the thesis which is to be developed here that criteria for the pathological diagnosis of cirrhosis should be clearly defined. There has been a strong tendency in recent years (*see*, for instance, the Report on the Fifth Pan-American Congress of Gastroenterology, 1956, *Lancet*, i, 377) to accept only those lesions in which the normal lobular pattern of the liver has been replaced by nodules of regenerated parenchyma separated by a more or less well-developed reticulum of fibrous tissue. Disorganization of normal lobular architecture is the essential feature of cirrhosis, fibrosis being fundamental only to the extent that it contributes to this. It follows that minor grades of hepatic fibrosis with a normal lobular pattern should not be called cirrhosis. This definition of cirrhosis has a sound theoretical basis (Parker, 1956); it also has the great practical merit that it brings into close accord the clinician's and the pathologist's concepts of the condition. One is bound occasionally to encounter borderline lesions in which the normal lobular pattern has not been entirely destroyed: these, however, are nearly always incidental—and often unexpected—findings at necropsy, although in some cases of post-necrotic cirrhosis (the healed yellow atrophy of older writers)—there may be some retention of lobular pattern in the regenerated parenchyma even though in other respects these cases may be both clinically and pathologically fully developed examples of cirrhosis.

In all but one of the hepatic carcinomas accompanying cirrhosis in this series the diagnosis of malignancy was established by the presence of extrahepatic metastases or of invasion of veins within the liver (frequently both these features were found). In the single exception it rested upon cytological atypicality alone.

In Table I are analysed all cases of primary hepatic carcinoma coming to necropsy in the

TABLE I.—CLASSIFICATION OF PRIMARY HEPATIC CARCINOMA, (LONDON HOSPITAL, 1919–1955)

Morphological category	Total	Number associated with cirrhosis	Number occurring in males
Liver-cell carcinoma	32	27 (84·4%)	29 (90·6%)
Bile-duct carcinoma:			
hilar in 11; peripheral or multinodular in 6..	17	1 (5·9%)	11 (64·7%)
Histologically doubtful carcinoma	3	1 —	1 —
Mixed liver-cell and bile-duct carcinoma ..	1	1 —	1 —
Total	53	30 (56·6%)	42 (79·2%)

London Hospital from 1919 to 1955. There were 53 such cases among 17,732 necropsies, an incidence of 0·30%, which is not unusual (Berman, 1951; Meyer, 1954). In other respects, too, the figures in Table I could be matched in whole or in part by those of many previous reports. Thus the high incidence of cirrhosis as an accompaniment of liver-cell carcinoma is well known, as is the fact that most patients with this type of carcinoma are men. Of 30 carcinomas associated with cirrhosis in this series, 27 were in males. Although this striking differential sex incidence is well recognized, its implications have not always been appreciated.

In Table II the problem has been approached from the opposite viewpoint, namely the

TABLE II.—INCIDENCE OF CARCINOMA IN CIRRHOSIS

	Total	Number with carcinoma
All cases of cirrhosis diagnosed at necropsy	184	30 (16·3%)
Fatal cirrhosis	134	25 (18·6%)
Incidental cirrhosis	50	5 (10·0%)

incidence of primary hepatic carcinoma in a series of cirrhotics. In the years 1919 to 1955, 184 cases of cirrhosis came to necropsy at the London Hospital, and in 30 (16·3%) of these there was malignant change. This is a figure some four times greater than the lower of those given by Stewart (1931), or than that usually accepted in the American literature (Gall, 1956). When one considers only those cases in which cirrhosis was more or less directly the cause of death (termed fatal cirrhosis in Table II) the incidence of carcinoma is even higher, namely 18·6%.

The sex incidence of carcinoma complicating cirrhosis is considered in Table III. It will

TABLE III.—CARCINOMA AND CIRRHOSIS—SEX INCIDENCE

	Total	Number with carcinoma
All cases—males	114	27 (23·7%)
All cases—females	70	3 (4·3%)
Fatal cirrhosis—males	74	22 (29·7%)
Fatal cirrhosis—females	60	3 (5·0%)
Incidental cirrhosis—males	40	5 (12·5%)
Incidental cirrhosis—females	10	0 —

be seen that malignant change occurs among male cirrhotics far more frequently than among females, the respective percentages for fatal cirrhosis being 29·7 and 5. In the series as a whole, 23·7% of males developed hepatic carcinoma.

In Table IV cases of fatal cirrhosis are divided on an ætiological basis. Incidental cirrhosis

TABLE IV.—CIRRHOSIS AND CARCINOMA—ÆTIOLOGICAL CLASSIFICATION

Ætiological category	Fatal cirrhosis Total number	Number with carcinoma
Cause undetermined	61	10 (16·4%)
Post-hepatitic cirrhosis	36	1 (2·8%)
Post-necrotic cirrhosis in 25 (a history of hepatitis in 15 of these); Laënnec's cirrhosis in 11		
Alcoholism	30	10 (33·3%)
Hæmochromatosis	2	2 —
Primary biliary cirrhosis	2	0 —
Fanconi's disease	1	1 —
Chiari's syndrome	1	1 —
Cinchophen poisoning	1	0 —
Total	134	25 (18·6%)

has been excluded from this analysis because of relative inadequacy of the clinical records. It will be seen that even in fatal cirrhosis there was a substantial number of cases, nearly one-half, in which there was no reliable clue to the ætiology of the hepatic lesion. Post-hepatitic cirrhosis accounted for about a quarter of the total, and in this group the incidence of carcinoma was very low. Although the criteria adopted for including lesions in this category were fairly strict, it is apparent that the diagnosis was not equally well established in all cases. The only example of primary hepatic carcinoma in this group occurred in a man of 60 with Laënnec's cirrhosis and a history of jaundice forty years previously. It cannot of course be proved that the jaundice and cirrhosis were causally related. There are in the literature examples of post-hepatitic cirrhosis complicated by carcinoma (Walshe and Wolff, 1952; Sheldon and James, 1948), but the figures cited here, taken with those of Stewart (1931) suggest that malignancy rarely supervenes upon this type of cirrhosis. The rather higher proportion of females in the post-hepatitic cases than in the series as a whole may have a bearing on this. More important perhaps is the relatively short duration of post-hepatitic cirrhosis (or at least of those cases in which the diagnosis can readily be made). In the 15 examples of post-necrotic cirrhosis with available clinical data included in Table IV, the average interval between the initial attack of hepatitis and death from cirrhosis was only three years.

In chronic alcoholism, on the other hand, the incidence of carcinoma in this series was very high, namely 33·3%. In comparing alcoholic and non-alcoholic cirrhosis a figure of this magnitude was liable to occur by chance in only 1 of every 25 samplings. But after allowing for the fact that 24 of the 30 alcoholics, including all those with carcinoma, were males, the possibility of this difference having occurred by chance was raised to about 1 in every 7 samplings. It is quite possible therefore that the high incidence of malignant change among the alcoholics of this series merely reflected the sex incidence of alcoholic cirrhosis. The supposed high incidence of liver cancer in hæmochromatosis may have a similar explanation, for hæmochromatosis is very largely a disease of males. Warren and Drake (1951) deduced from the literature that this incidence was 18·9%, a figure which they considered to be more than four times that for cirrhosis in general; this figure is, however, appreciably less than that for males in the present series.

Finally an explanation must be sought for the differences between the figures set forth here and those in previous reports on the subject. It may well be that many of these differences are apparent rather than real, being due to use of the term cirrhosis for minor degrees of hepatic fibrosis without disruption of lobular pattern and without the clinical picture of the disease. It is claimed, however, that there are geographical variations in the liability of cirrhosis to undergo malignant change (Report of Conference on Liver Cancer, 1956, *Lancet*, ii, 782). In North America this liability is said to be lower than in Europe; but there is in the literature some evidence to the contrary. Thus Edmondson and Steiner (1954) found hepatic carcinoma in 4·5% of all cirrhotics, but in 19% of advanced atrophic cirrhosis. The corresponding figures of Wilbur *et al.* (1944) are 10·5 and 14·2%. Figures in excess of 10% are also given by Loesch (1939) and McNamara *et al.* (1950). Thus it may well be that uniform standards for the diagnosis of cirrhosis would result in similar figures for both America and Europe. Carcinoma as a complication of cirrhosis in tropical countries will not be discussed here.

Summary

Primary carcinoma of the liver was present in 16·3% of 184 patients in whom cirrhosis had been diagnosed at necropsy. When only those patients actually dying of hepatic disease were considered, the incidence of malignant change was 18·6%. Corresponding figures for male cirrhotics alone were 23·7 and 29·7% respectively.

Post-hepatitic cirrhosis is seldom complicated by primary hepatic carcinoma. Its high incidence in alcoholic cirrhosis and in hæmochromatosis may depend on the fact that most patients with these diseases are males.

Pseudocholinesterase in Early Infancy

By H. LEHMANN, M.D., Ph.D., F.R.I.C., JOSEPHINE COOK, M.B., B.S., D.C.H., and ELIZABETH RYAN, B.Sc.

St. Bartholomew's Hospital, London

PSEUDOCHOLINESTERASE

PSEUDOCHOLINESTERASE is an enzyme present in the serum which destroys acetylcholine *in vitro*. It is not identical with the true cholinesterase of the red cells which hydrolyses acetylcholine at physiological concentrations. We determined the activity following Jones and Tod (1935) and McArdle (1940) by incubating serum with acetylcholine and a $NaHCO_3$ buffer in a micromanometer. On hydrolysis of acetylcholine to choline and free acetic acid one mol of CO_2 is liberated from $NaHCO_3$ for each mol of free acetic acid, and the CO_2 is measured manometrically. According to McArdle (1940) one unit of enzyme equals one μl. of CO_2 liberated by one ml. of serum in one minute at 37° C. Our normal range in adults is 75–125 units with a mean of 85 units.

Normal Pseudocholinesterase Levels in Adults, Children and Infants

It is well known that the normal pseudocholinesterase level shows great individual variation in adults, although it remains very stable from day to day in any one individual (Vereby, 1936; Hall and Lucas, 1937; Antopol *et al.*, 1937; McArdle, 1940; Sawitsky *et al.*, 1948; Callaway *et al.*, 1951; Kaufman, 1954). There is in adults no correlation between age and pseudocholinesterase level. The normal level in children is not as well defined as that of adults. Rather high values have been reported in children by McArdle (1940) who in 40 normal adults found a range between 51 and 121 units with a mean of 78, and in 20 children aged between 7 and 15 years observed a range between 71 and 166 units with a mean of 105 units. Although there is a considerable overlap between the values found in the two groups the overall difference is statistically significant. Hodges (1956) compared 52 healthy adults and 70 healthy children aged 3–10 years. The number of high values was greater among the children, but the differences were not significant statistically. Our own experiences are the same as those of Hodges. In contrast to children where the pseudocholinesterase level is if anything higher than in adults, low enzyme activity has been reported in newborn infants by Faber (1943) and McCance *et al.* (1949). Stead (1955) mentions that he has found the pseudocholinesterase level of the neonate at times to be as low as 40% of the adult mean.

Liver Function and Pseudocholinesterase Level in the Newborn

It is now accepted that a low pseudocholinesterase level can be an indication of lowered liver function. McArdle (1940), Wescoe *et al.* (1947), Kaufman (1954) and Hunt and Lehmann (1956), among others, have demonstrated the changes of pseudocholinesterase level with improvement or deterioration of liver function. It occurred to us that the low pseudocholinesterase level found at birth might be related to incomplete development of liver-cell activity—just as functional immaturity of the liver cell has been held responsible for the physiological hæmolytic jaundice of the newborn, the liver at birth being thought to be unable to metabolize an amount of bilirubin arising from red cell breakdown with which it would easily cope at a later age.

Mollison and Cutbush (1949) injected 5 mg. of bromsulphalein per kilogram of body weight into healthy adults and found that the liver removed 98% of the drug from the blood stream within one hour. In newborn infants receiving the same dose there was an average retention of 15% of the dye two hours after the injection. These results were interpreted as an indication of an immaturity of the excretory function of the newborn liver. They were in support of earlier work of Herlitz (1926) who also had described an abnormal bromsulphalein retention in the newborn, but they contradicted the observations of Salmon and Richman (1943) who had failed to do so. Yudkin *et al.* (1949) tested the bromsulphalein excretion in infants from 8 hours to 8 days old and found a higher proportion of normal values above the age of 4 days than below that age.

To obtain exact information on the pseudocholinesterase levels of infants seemed to us valuable not only for theoretical reasons but also from the practical point of view. In the diagnosis of neonatal hepatitis it is important to know what constitutes an abnormally low level in infants. Mollison and Cutbush (1949) and Yudkin *et al.* (1949) had not found a correlation between the degree of failure to excrete bromsulphalein at birth and the subsequent rise in bilirubin levels. We had hoped that the pseudocholinesterase level at birth might perhaps serve as a measure predicting the failure to metabolize bilirubin later on.

Results

We examined 87 cord bloods of which 43 were obtained at St. Bartholomew's Hospital and the remainder from Queen Charlotte's Maternity Hospital. It will be seen from Table I

Table I.—Pseudocholinesterase and Birth Weight

Weight lb.	Number	Mean (units)	Range (units)	Number	Mean (units)	σ
2–3	9	55	35–104			
3–4	10	55	37– 81	43	59	±15
4–5	24	62	34– 93			
5–6	16	62	36– 86			
6–7	13	55	38– 71	29	59	±13·3
7–8	9	66	38–110			
8–9	6	76	41–101	15	70	±22·2

Pseudocholinesterase levels in newborn infants.

that many values were below those considered normal in adults. The mean value was higher the greater the birth weight, but with all birth weights the lower range extended below the

normal adult range. In 61 of the 87 children definite information could be obtained on the duration of gestation, in addition to that of the birth weight. Table II shows that there was

TABLE II.—PSEUDOCHOLINESTERASE IN INFANTS

Age	Number	Mean (units)	Range (units)	σ
At Birth				
Premature ..	30	59	35–104	±16·6
Full term	31	66	38–110	±17·2
1–4 weeks	10	86	60–105	±15·9
4–8 weeks	14	94	68–150	±21·9

no difference when cord bloods of 30 premature and 31 full term babies were compared. Of the premature babies 6 had been born after a pregnancy lasting less than 30 weeks, and 24 after one lasting 30–35 weeks. There was also no difference in the results obtained in these two groups of premature infants. Table II also shows that in contrast to the newborn the pseudocholinesterase level in infants aged 1–8 weeks was within the range considered normal for adults and that in the group aged 4–8 weeks there was a number of children with a level higher than normal adult levels.

In view of the wide individual variation a much larger number of infants would have to be investigated to obtain statistically significant data supporting a rise of pseudocholinesterase level within the first few weeks of life. We decided therefore to examine the enzyme levels over the first weeks of life in 22 infants individually. These had been born at full term with a normal birth weight and were not jaundiced. Fig. 1 illustrates the results; the values

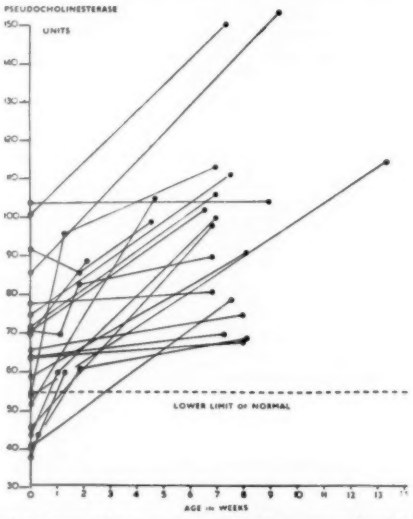

FIG. 1.—Serial observations on pseudocholinesterase level in 22 normal infants during the first weeks of life.

obtained at birth (but not those obtained later) are also included in Tables I and II. It will be seen in Fig. 1 that 8 of the 22 infants showed levels of 55 units and below at birth, and that the highest level was 104 units. With one exception, where at birth and just above nine weeks later the level was 104 units, all infants examined after one month showed a higher enzyme concentration than at birth. Within the second month of life all of 20 infants seen were found to have levels within the normal range. Furthermore whereas at birth only three values of 22 had been above 90 units, within the second month of life 13 of 20 were above this level.

The samples obtained at birth were cord blood, and those obtained later were capillary blood. Fig. 1 illustrates that the change from the enzyme concentration at birth to that seen later was gradual and could not be due to a difference between cord and capillary blood. It will be seen that in one instance the level rose from 38 units at birth to 44 units after two and to 60 units after nine days.

Unfortunately no correlation between pseudocholinesterase level at birth and subsequent rise of bilirubin level was found. On the other hand our observations allow the suggestion that except for the first few days of life a low pseudocholinesterase level can be taken to be pathological in infants as well as in adults. This conclusion has helped us on several occasions in the diagnosis of jaundice in infants, and has so far never failed us.

Conclusions

The pseudocholinesterase level was measured in the serum of 87 newborn infants. Whereas in adults the normal range is 55–125 units, the range in the newborn was 34–110 units. There was no difference between premature and mature newborn infants, and no correlation could be found between pseudocholinesterase level at birth and subsequent rise in bilirubin level.

In 24 normal infants aged 1–8 weeks the range was 60–150 units, and the low pseudocholinesterase level at birth is correlated with an immaturity of liver function as previously demonstrated by the measurement of bromsulphalein excretion.

Serial observations were made on 22 infants. 8 of them at birth had pseudocholinesterase levels lower than would be considered normal in adults. All values were normal when the infants were re-examined later on. Whereas only 3 of the infants had at birth a pseudocholinesterase level above 90 units, 13 such values were found in 20 infants re-examined within the second month.

It is suggested that after the first few days of life an abnormally low level of pseudocholinesterase can be considered pathological.

Acknowledgments

We should like to thank Dr. C. F. Harris and Dr. A. White Franklin for permission to investigate infants under their care and Dr. G. H. Lathe for sending us sera from infants under examination for jaundice in the Bernhard Baron Laboratories at Queen Charlotte's Maternity Hospital.

President—ERIC A. CROOK, M.A., M.Ch., F.R.C.S.

[*November* 7, 1956]

Post-Traumatic "Tumour" of Stomach.—J. T. CHESTERMAN, F.R.C.S.

This patient, a well-built man aged 29 and a fitter erector by occupation, fell prone some 12 ft. off scaffolding and while lying on the ground, a 15-cwt. metal container rolled across the left lower chest, pinning him down.

I first saw him some eight hours later when his presenting symptom was dyspnœa. He had a tension pneumothorax on the left side but no fracture or other obvious gross lesion. The tension pneumothorax could not be relieved for more than one hour or so by needle aspiration so an intercostal catheter was inserted. However, some hours later he suddenly became breathless again so a little barium was given by mouth and a further X-ray film taken which showed the stomach and intestine herniated into the left thoracic cavity. Also, he developed hæmaturia and right-sided renal pain.

At thoracotomy (6.2.54), the stomach, parts of the small and large intestine were reduced, the spleen was removed on account of a tear in the upper pole, which, however, had not bled, and the diaphragm was sutured. No gross lung lesion was found. Recovery was uneventful and the patient returned to work fourteen weeks later.

Seven months after the accident he started suffering from acid regurgitation only when lying down and after taking certain foods such as pastry and plums, but by a year later posture alone was the determining factor in the occurrence of regurgitation. This did not bother him much until two and a half years after the accident, when vomiting started to take place at any time and in any position and was associated with epigastric cramp, perspiration, throbbing in the head and trembling in the legs. Relief only occurred after vomiting about 5 oz. of what appeared to be gastric juice. (Routine blood and urine analyses showed nothing abnormal.)

A Ba meal examination suggested a lesion in the fundus of the stomach (*see* Fig. 1). Gastroscopy showed hypertrophic folds running towards the fundus but was not conclusive. A diagnosis of benign tumour was made.

FIG. 1.—Barium meal showing localized muscular hypertrophy of the fundus of the stomach at the site of adhesion to the diaphragm.

Operation (16.10.56).—The stomach was approached through the old thoracotomy incision and a localized mass felt through its wall exactly opposite to an area of dense non-vascular fibrous union of the fundus of the stomach to the diaphragm. The stomach was freed and the "tumour" excised. Recovery has been uneventful and the patient can now take normal diet and remain in any position without discomfort (7.11.56).

Pathological report.—"A piece of gastric mucosa. Does not look markedly neoplastic but the muscle tissue seems abundant. Histological examination shows an intact but rather hypertrophied mucosa. Beneath this is a mass of normal-looking smooth muscle. It is not encapsulated and merges into the surrounding tissue. Groups of sympathetic ganglia are identifiable in the interstices. This suggests to me that this is not a true leiomyoma but a localized hypertrophy."

CONCLUSION

This appears to be a localized muscular hypertrophy of the stomach at the site of a fibrous union with the diaphragm which gave rise first to incompetence of the cardia and later, intermittent obstruction.

Neurofibroma of the Sacral Plexus.—R. S. HANDLEY, O.B.E., F.R.C.S.

A woman of 25 complained that since the age of 10 she had suffered intermittent "electric" pains shooting down her left leg sometimes reaching the great toe. They were worse if she were constipated or if she lay on her left side. The pains had recently increased to the point of being a considerable nuisance. No orthopædic cause for the symptom was found by Mr. Philip Kerr, F.R.C.S., who referred her, but he had discovered a mass in the pelvis.

Full examination showed no abnormality except for the pelvic mass, which was clearly extra-rectal, fixed to the side wall of the pelvis, smooth, rubbery-hard, and apparently about the size of a flattened hen's egg. Palpation of it *per rectum* caused the tingling pain down the leg of which the patient complained. A sacral plexus neoplasm, probably a neurofibroma, was diagnosed.

With the patient in a steep Trendelenburg position, the peritoneal cavity was opened by a low left paramedian incision. The upper half of the tumour was easily seen. The peritoneum over it was incised and it was enucleated by blunt dissection, mostly with the finger. Venous oozing was checked by a pack, followed by implantation of gelfoam. Apart from a small hæmatoma, recovery was uneventful and the symptoms were completely relieved.

The specimen was a faintly lobulated tumour, measuring 3 in. by 2 in. by 1 in. and sections showed a typical, fairly cellular neurofibroma.

Traumatic False Aneurysm of the Posterior Tibial Artery.—E. C. B. BUTLER, F.R.C.S.

Male, aged 21. Four months before admission, patient had sustained a fractured right tibia and fibula which had been treated by plating. For six weeks there had been increasing swelling and aching of the right calf.

On examination.—There was good union of the fractured bones, and an obvious swelling of the right calf which had a bruit on auscultation. Arteriogram confirmed the presence of a large aneurysm arising from the posterior tibial artery.

11.1.56: A vertical incision was made down the back of the calf splitting the gastrocnemius and soleus muscles. A large false aneurysmal sac was found over which was stretched the posterior tibial nerve. When the clot had been cleared away a small hole was seen in the posterior tibial artery; this was still patent and pulsating. The posterior tibial artery was ligated. Directly under the site of the injury to the artery was the point of a screw. The wound was sutured with drainage. The patient made a good recovery and had excellent arterial circulation to his leg.

Comment.—(1) The injury to the artery may have occurred at the time of operation or it may have been due to gradual erosion of the posterior tibial artery by the point of the screw. (2) The approach to the aneurysm by splitting the soleus and gastrocnemius muscles gave an excellent exposure without damaging the ultimate functions of these muscles.

Malignant Hæmangioblastoma of Liver. Total Excision of Right Lobe of Liver.—RODNEY SMITH, M.S., F.R.C.S.

Mrs. E. P., aged 65. Five months' history of breathlessness, exhaustion, swelling of abdomen, swelling of ankles, pain in upper right abdomen. Examination revealed huge irregular enlargement of liver. Liver function tests normal. X-ray of chest showed gross elevation of right diaphragm. Liver biopsy attempted twice. Blood-stained fluid obtained. Cholecystogram: No gall-bladder seen.

Operation I (14.10.56).—Upper right paramedian incision. Huge cystic tumour occupying whole of right hepatic lobe. Left lobe apparently clear. Evisceration, packing and marsupialization of largest cyst, with piece of wall for biopsy. Report: Malignant hæmangioblastoma.

Operation II (1.11.56).—Hypothermia induced. Right thoraco-abdominal incision. Total excision of right lobe of liver (Fig. 1).

Procedure.—Dissection in the porta hepatis, ligation of cystic duct, right hepatic duct, right branch of hepatic artery, right branch of portal vein. Division of peritoneal attachments of right lobe. Liver divided between right and left lobes with great care in order to secure all right hepatic veins draining into the inferior vena cava and preserve the middle and left hepatic veins. Detached right lobe removed. Abdomen closed with drainage.

FIG. 1.—Resected right lobe of liver. Dotted area shows line of section between right and left lobes.

Progress.—Liver function tests on the fourth post-operative day gave normal values. Patient has made a good recovery, but a rare complication of hypothermia (venous gangrene of a hand) has led to a longer stay in hospital than expected.

(A detailed report of this case is to be published elsewhere.)

[*December* 5, 1956]

DISCUSSION ON THE PROBLEM OF THE RESISTANT ORGANISM AND CHEMOTHERAPEUTIC SENSITIVITY IN SURGERY

Professor F. Linder (Berlin): In view of the relatively minor changes in operative technique, the remarkable progress in surgery, which has been achieved during recent years, seems to be largely due to three factors. These are: (1) Improved methods of anæsthesia; (2) replacement of blood, fluids and electrolytes; (3) chemotherapy.

As a result, the operative risk in the commoner operations, e.g. gastrectomies, has been lowered, in spite of a higher average age of the patient. Furthermore, the development of a whole series of new operations, in the thorax, upon the heart and great vessels has been facilitated. These three factors, mainly due to Anglo-American medicine, have become effective in Germany only since the end of the Second World War. Since these factors became operative all over the world within a relatively short space of time, the evaluation of antibiotics alone is difficult.

In the fight against surgical infections chemotherapy has come close to a triumph. Colebrook in England was the first to treat streptococcal septicæmia successfully with the sulphonamides of Domagk. Penicillin, developed in this country, was the first effective weapon against staphylococci. To-day antibiotics have partially or completely replaced some operations, e.g. for early osteomyelitis, and in others they have reduced the risk of operation. But the antibiotics are not free from harmful side effects. As with all drugs, we differentiate three groups of reactions:

(1) *Toxic reactions*—which are avoidable by strict attention to dosage.

(2) *Allergic reactions* which, independent of dosage, can lead to anything from a mild skin reaction to death. In 1955 my colleague Goetze was able to collect 53 fatal reactions to penicillin alone, from the world literature.

(3) *The third group* comprises non-specific side effects, to which belongs the increase in resistant organisms. This has led to a breach in our antibiotic defence. Superinfection with resistant, or less resistant, organisms, has given rise not only to new therapeutic problems, but has unfortunately brought a threat to the life of many a patient.

I shall give some clinical pictures of resistant strains and superinfection as they occur in the daily practice of a general surgeon. I shall also discuss the indications for antibiotic therapy in surgery, since the indiscriminate use of antibiotics has led to the present state of affairs, making restrictions necessary.

A *survey of the surgical bacteriology* gathered from non-selected examinations of wounds, sputa, pleural aspirates and urine during the last four years in my clinic (Fig. 1) reveals the predominance of hæmolytic *Staphylococcus aureus*, whose resistant strains have set us new problems as everywhere else in the world. The part played by the hæmolytic streptococcus is infinitesimal in comparison; it has fortunately lost little of its sensitivity and therefore seems to be clinically benign. A larger section is made up of *Esch. coli*, proteus and pyocyaneus, which belong, as does the tubercle bacillus, to a group of organisms which respond only slowly or incompletely to chemotherapy and often become resistant. About 5% are due to *Candida albicans*, although this is only rarely a pathological finding, being mainly saprophytic; but if antibiotic therapy, especially with tetracyclines, is allowed to disturb the equilibrium of organisms, the living conditions of this fungus can be considerably improved. Best known are the ano-genital skin lesions.

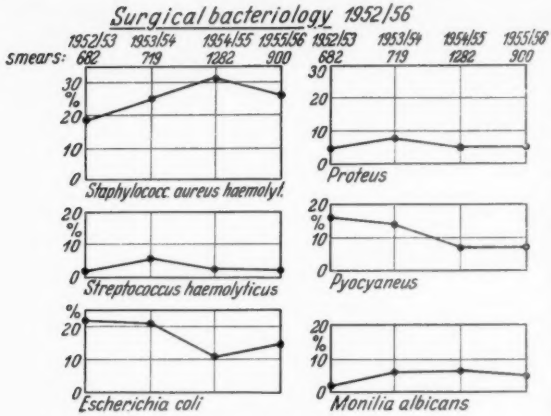

FIG. 1.

Rarer, but more serious, are internal, septicæmic *monilial infections*, which have been seen in practically every organ. We saw a single, severe case of pulmonary moniliasis in an adult, who had been treated for weeks with all available antibiotics as his pneumonia was slow to resolve. Rupture of bronchopneumonic monilial abscesses had led to bilateral pneumothorax. The cessation of all antibiotics and bilateral aspiration-drainage brought a gradual improvement of his serious condition.

The *existence of chronic anatomical lesions*, e.g. soft-tissue fistulæ, bone cavities, bronchiectasis, predisposes to the appearance of resistant organisms. The treatment of these lesions with antibiotics alone is useless in most cases. If the attempt is made, superinfection with resistant organisms is almost inevitable. A case based on a pinned and infected pseudarthrosis of the femur will illustrate this old story. The bacterial flora of this bony fistula was followed up for over two years. At first the staphylococcus showed a satisfactory sensitivity to penicillin. This was lost and the tetracyclines also failed in the end. The *Esch. coli* went through the same stages. Finally, *Proteus vulgaris* came along, often in pure culture and was soon resistant to all the then available antibiotics and sulphonamides. A cure was achieved only after it was possible to eradicate the focus of infection surgically. Another organism, which often perpetuates infection after prolonged antibiotic therapy is the *B. pyocyaneus*. After the destruction of the primary infecting agent, this saprophyte can become pathogenic and so maintain the infection—often in pure culture. A typical example can sometimes be observed after lung resections with consequent infection of the pleural cavity. In some cases this pyocyaneus infection can be cured by aspiration and instillation of polymyxin B only.

For the surgeon, the chief problem of bacterial resistance is presented by the behaviour of the hæmolytic *Staphylococcus aureus*. As is generally known, its resistance has rapidly increased all over the world parallel to the increase in antibiotic therapy. This development was delayed in Germany for obvious reasons. In Berlin penicillin was available in unlimited quantities only after the end of the blockade in 1949. Thereafter, our staphylococci also rapidly became adapted and by 1955 the sensitivity of staphylococci in our own clinic showed a resistance to penicillin and streptomycin in 72% and 60% of the strains tested. With tetracyclines, resistant strains were 33% approximately. With erythromycin (6%), neomycin (0%) and especially with the new oleandomycin (0% resistant strains) the position is still favourable at present. In 1956 the sensitivities to the usual antibiotics have remained unaltered, but the erythromycin-resistant strains have unexpectedly disappeared. We attribute this to our again more frequent use of chloramphenicol, so that erythromycin was used only as a last resort. The regression of bacterial resistance under antibiotic rotation-therapy appears as a ray of sunlight in the dark skies of this deplorable chapter.

Nowhere has the epidemiological significance of resistant staphylococcal strains been followed up more thoroughly or with more success than in this country. Authors like Blowers, Colebrook, Hare, Lowbury and Shooter, amongst others, have not only studied the ways of transmission of these germs in hospital, but have also given valuable advice on the prevention of this new plague. Fundamentally it is also our experience that the carrier rate amongst the new admissions rises from 30% to 70% within a few days, even when these patients have not received any antibiotics. The proportion of nasal carriers among our own personnel is shown in Fig. 2. Repeated examinations in 1956 showed a retrograde tendency, although, so far, no carriers have received local therapy. Perhaps this can be explained by a simultaneous decrease in the use of antibiotics, to which I shall refer later.

As a result of the ubiquitous presence of resistant staphylococci in hospital, endemic infections of the most varied localizations are known. First there are the *furunculoses of the skin*, which often cause more suffering to the patient than the initial operation itself. Also *post-operative parotitis*, which became quite unknown during the first years of anti-

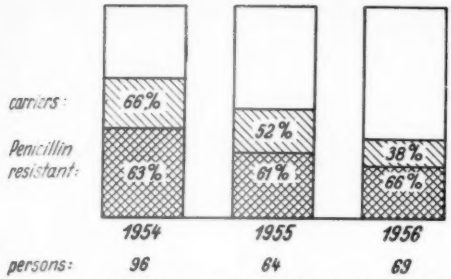

FIG. 2.—Nasal carriers of staphylococci amongst hospital staff, Chirurgische Klinik der Freien Universität Berlin.

biotic prophylaxis, is coming to the fore again. In the course of a single year we have observed 14 cases (0·8% of all operations). In the majority, hæmolytic staphylococci, always resistant to penicillin and often resistant to tetracyclines, were found either in the mouth or in the pus obtained from incision.

The local instillation of neomycin and bacitracin into the Stensen's duct of the inflamed gland has been of use only in the very early stages of the disease. Commonly we give parenteral or oral erythromycin and lately a combination of tetracycline with oleandomycin. In this way we hope to combat the resistant staphylococci and also the Gram-negative bacteria since we have had four cases with a pure culture of *Aerobacter aerogenes*. Naturally, according to a principle of chemotherapy, success can only be achieved if a sufficient concentration of the antibiotic reaches the site of infection before sequestration of the gland has taken place.

The same therapy has been successful in resistant *staphylococcal pneumonia*. We must bear this condition in mind whenever post-operative lung-infiltrations are slow to resolve. Not infrequently there is abscess-formation—as in a case we had after a mitral commissurotomy—which can, however, heal completely under conservative therapy. Another superinfection with resistant staphylococci is *pseudomembranous enterocolitis*. This clinical picture is not solely the result of antibiotic therapy, as it had been described, as far back as 1893, by Finney. Nevertheless, this syndrome, as a result of treatment with broad-spectrum antibiotics and sometimes also of parenteral penicillin and streptomycin therapy, has increased since its first description by Kramer in 1948. According to the simplified explanation of Poth, antibiotic therapy suppresses the normal intestinal flora, so that strains of staphylococci, usually acquired by cross-infection, can grow without hindrance and, through the release of their highly poisonous enterotoxin, produce this serious syndrome. In 1955 Senn collected 83 cases from the world literature, which surely represent only a fraction of the actual disaster. Therapy with erythromycin or oleandomycin, by replacement of fluids and electrolytes and with ACTH and noradrenaline can save only a small proportion of these cases.

A further serious consequence of the hospital strains of staphylococci seems to be the *increased rate of wound infections*, as reported so frankly from several clinics (Howe; Blowers; Shooter). Our own proportion, in 1956, of 2·9% minor and 2·9% severe infections surpasses what we were accustomed to in the pre-antibiotic era.

Table I shows the distribution of responsible organisms in 30 infected cases after aseptic

TABLE I.—SENSITIVITY OF ORGANISMS FOUND IN 30 WOUND INFECTIONS AFTER ASEPTIC OPERATIONS, 1956

Organism	No.	Sensitivity tests	Resistance to: Penicillin+ streptomycin	Tetracycline	Neomycin	Erythromycin	Polymyxin
Staphylococcus aureus	17	12	8	4	—	—	—
Staphylococcus albus	2	1	1	—	—	—	—
Streptococci							
(1) *β-hæmol. str.*	1	1	—	—	—	—	—
(2) *α-hæmol. str.*	1	1	—	—	—	—	—
(3) *Enterococcus*	3	2	1	1	—	—	—
(4) *Pneumococcus*	1	1	—	—	—	—	—
Escherichia coli	9	9	3	3	—	—	—
Proteus	2	2	1	2	—	—	—

operations, amongst which the staphylococcus accounted for over 50%. The signs of fever and local inflammation were inhibited in a considerable proportion by antibiotic prophylaxis.

So much for the present situation, which has given rise to serious problems in surgery also. For their solution several measures are required. First there are those directed against the

spread of resistant organisms in hospital, which have already been effectively applied in his country. The continual introduction of new antibiotics cannot lead to any fundamental change in the situation. Rather it would seem necessary to reduce the present extent of antibiotic therapy to reasonable proportions.

In this connexion, the following is a short survey of the surgical indications for antibiotic therapy, as gathered from the literature and personal experience. Fundamentally we can differentiate two types of antibiotic therapy: (1) The prophylactic, and (2) the curative indications. Since the results of the *curative group* can be more clearly evaluated, it is shown first in Table II.

TABLE II.—CURATIVE ADMINISTRATION OF ANTIBIOTICS

(1) Surgical infections
  (*a*) often without operation: erysipelas, anthrax, osteomyelitis, face furuncle, cellulitis
  (*b*) as adjunct to surgery: perforated appendicitis, perforated peptic ulcer
(2) Wound infections after trauma or surgery
(3) Pulmonary and extra-pulmonary tuberculosis
(4) Local administration (often combined with systemic administration):
  pyogenic joint infection, pleural empyema, osteomyelitis, contaminated wounds

There is no doubt that many surgical infections take a more favourable course with modern chemotherapy. Nevertheless the old dictum "ubi pus, ibi evacua" still holds good. Even now osteomyelitis has by no means become a medical disease. In perforation peritonitis chemotherapy has, in my opinion, proved of value. On the other hand, it is interesting that, in the treatment of chronic typhoid carriers, chloramphenicol has failed completely, in spite of a high sensitivity of the organisms, and in spite of such great success in the acute illness. The surgical removal of diseased gall-bladders, on the other hand, gives a cure rate of 90%, as prolonged follow-up of 130 cholecystectomized patients has shown in Berlin. In serious wound infections only, and after previous sensitivity tests, parenteral chemotherapy should be used.

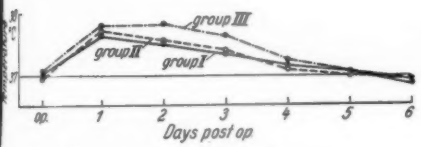
Table III shows the indications for the *prophylactic use of antibiotics*. It is in this field above all others, that great restraint is essential, as in many hospitals often the greatest proportion of antibiotics is given for this reason.

TABLE III.—PROPHYLACTIC USE OF ANTIBIOTICS

(1) War wounds
(2) Special accidental wounds: compound fractures, skull base fractures, burns, &c.
(3) Aseptic operations of
  (*a*) brain, heart; on bones, joints, &c. (but no antibiotics for hernias, thyroidectomies, sympathectomies or breast amputations)
  (*b*) lung, œsophagus, cardia, stomach, colon, infected bile duct and genito-urinary tract
(4) Operations in contaminated areas: amputation of gangrenous leg, carcinoma of penis
(5) Emergency operations in patients with infection outside surgical illness

In gun-shot wounds prophylactic chemotherapy seems justified, because only rarely is complete excision of the wound possible. The position is different with excised and sutured accidental wounds, the healing rate of which cannot be significantly improved by local or parenteral administration of antibiotics. Nevertheless, antibiotic prophylaxis is justified in certain special injuries as shown in Table III. The most controversial group of antibiotic prophylaxis is provided by the aseptic operations. Two sub-groups must be distinguished: (*a*) The purely aseptic operations and (*b*) those operations in which, at some point, the interruption of asepsis is made probable, as by the cutting of a hollow organ.

In the large majority of purely aseptic operations, such as herniorrhaphies, thyroidectomies and so on, antibiotics are contra-indicated, as the number of wound infections cannot thereby be reduced. In cases with rheumatic or congenital heart lesions, we give penicillin post-operatively, so as to hold the streptococci in check. Neurosurgeons and orthopædic surgeons have practised a particularly generous prophylaxis in lengthy operations. To-day, as far as I know, this tendency is being reversed.

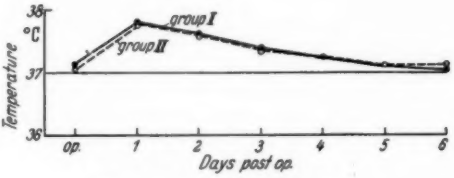


In lung resections we have, so far, given penicillin and streptomycin routinely (or we have been guided by pre-operative sensitivity tests) in order to prevent pulmonary or pleural infections. The danger of infection arising from a bronchial stump is, however, much smaller than expected, since bronchial swabs taken during operation for carcinoma or tuberculosis have proved to be sterile in 3 out of 4 cases. In surgery of the œsophagus and cardia, antibiotic prophylaxis has definitely reduced the danger of mediastinitis. Gastric resection, for peptic ulcer, is mostly a purely aseptic procedure. Through the action of acid

the stomach and first part of the duodenum or jejunum are sterile in 75% of cases. Therefore prophylaxis seems to be more indicated in cases of ulcerated and hypochlorhydric carcinoma of the stomach, in two-thirds of which our swabs have shown contamination with *Esch. coli*, staphylococcal or streptococcal organisms. On the other hand, gastric resections by the appropriate technique should provide no danger of contamination of the peritoneal cavity or of the abdominal wall.

Among operations on the colon, rectal amputations can be practically sterile from beginning to end. Therefore, only the resections with primary anastomosis make intestinal antisepsis desirable. We have tested all the drugs available for gut sterilization, including combinations of neomycin, and yet we still do not know if these drugs really produce better results than are achieved by a clean operative technique alone. Most antibiotics are excreted in high concentration in the bile and urine. They can therefore be used with success in the treatment of severe pericholecystitis, cholangitis or urinary tract infections. A simple cholecystectomy or nephrectomy obviously requires no prophylaxis.

Operations in infected, or previously infected, areas give an opportunity for specific prophylaxis, since, either before or during the operation, the sensitivity of the responsible organism can be tested. This field of application is not very big. Numerically the indications are even fewer in emergency operations on patients with a concurrent infection.



In order to test the value of prophylaxis in clean operations statistically, we have tried to compare identical groups of operations with and without antibiotics (penicillin and streptomycin post-operatively for five or six days). Such investigations are best done in a single clinic, since the selection of patients, operative technique and post-operative care, &c., can here be most easily compared.

Percentage of Wound Infections

	Severe	Mild	Total
Group I	1·2	5·3	6·5
Group II	—	5·6	5·6
Group III	5·0	5·0	10·0

FIG. 3.—Post-operative course of partial gastrectomies (benign ulcers). Group I: Prophylactic antibiotics, 170 cases, average age: 50·5 years. Group II: No antibiotics, 53 cases, average age: 50·4 years. Group III: Perforated ulcers with primary resection, average age: 48·3 years.

Percentage of Wound Infections

	Severe	Mild	Total
Group I	0·48	8·27	8·75
Group II	—	6·76	6·76

FIG. 4.—Post-operative course of cholecystectomies. Group I: 256 patients with antibiotic prophylaxis, average age 48·9 years. Group II: 59 patients without antibiotic prophylaxis, average age 50·2 years.

Fig. 3 shows the post-operative course of partial gastrectomy for peptic ulcer. The average evening temperatures of the test groups I and II are practically identical. Only in the group of primary resections for perforated ulcers (always treated with antibiotics) the temperatures lie higher. The number of wound infections in group II, which were not given antibiotics, was certainly not higher.

Results are similar with cholecystectomies. Here also neither the temperature chart nor the percentage of wound infections shows any advantage in antibiotic prophylaxis (Fig. 4).

Also other complications, such as bronchopneumonia or parotitis, are by no means rarer in patients who received post-operative prophylaxis. The figures are shown in Table IV.

TABLE IV.—COMPLICATIONS DURING POST-OPERATIVE COURSE
(Gastrectomies, Cholecystectomies, Thyroidectomies, Breast Amputations)
Group I: 621 patients with antibiotics
Group II: 158 patients without antibiotics

	Bronchopneumonias	Parotitis (gastrectomies and cholecystectomies only)
Group I	4·2%	1·85%
Group II	2·5%	1·69%

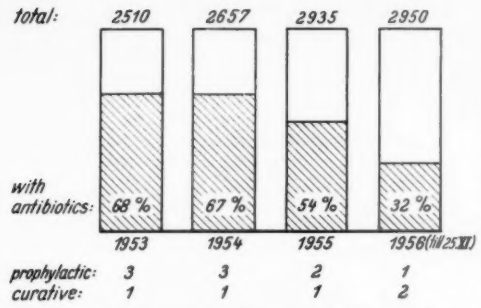


FIG. 5.—Rate of hospitalized patients who received antibiotics.

In our clinic we also have given antibiotics in abundance for a long time. It was not until the end of 1955 that we became more strict, due to the problems arising. The result of this policy is shown in Fig. 5. The total number of patients receiving antibiotics has lessened. The ratio of prophylactic to curative administrations has changed from 3 : 1 to 1 : 2 and will, I hope, sink still farther because even our residents have been convinced that this restriction is not only meant to cut down the expenses of the hospital.

In conclusion I would say that the value of chemotherapy in surgery is undoubted: but its indiscriminate use has created fresh problems. Asepsis has proved once more a fundamental principle in surgery for which chemotherapy—even partial—can never be a substitute.

Dr. R. A. Shooter: We have followed two types of infection in Professor L. P. Garrod's laboratory at St. Bartholomew's Hospital.

Treatment of Urinary Infections

Three years ago we carried out an investigation designed to see how well patients with urinary infections responded to chemotherapy, and how accurately laboratory tests of sensitivity to antibiotics forecast the eventual outcome of treatment (Garrod *et al.*, 1954). With the co-operation of the medical and surgical staff we collected records and examined specimens from nearly all the adult patients with urinary infections in or attending the hospital during eleven months. In uncomplicated infections there was good correlation between the cure rate and the guidance given by sensitivity tests, but for the series as a whole it was clear that what mattered primarily in the treatment of urinary infections was the condition of the patient's urinary tract. In the presence of stones or structural abnormalities or obstruction, the results were poor. Of the patients with abnormalities of this sort only 34% of males and 58% of females had sterile urine after treatment. On the other hand over 80% of the patients with no known abnormality and no previous history of urinary infection had sterile urine immediately after treatment. Between these two immediate cure rates was an interesting group composed of patients with no known abnormality, but with a history of previous infection.

I would like to put forward our experience with urinary infections as an example of resistance to treatment in which the patient is responsible rather than the resistant organism. An example of the other type of resistance, in which an infection is due to organisms resistant to the action of antibiotics, is provided by the present position with hospital staphylococci.

Staphylococcal Infections

Resistant staphylococci are resistant to penicillin because they form an enzyme, penicillinase, which destroys penicillin. One cannot make a staphylococcus resistant in this way to penicillin by exposing it to penicillin in the test tube or in the patient, and the resistant staphylococci which we now have in hospitals are the descendants, by selective breeding, of about 5% of pre-war strains. As a corollary to this, if a penicillin-resistant staphylococcus is isolated from an infection where before there was a sensitive staphylococcus, it nearly always represents the result of cross-infection by a new staphylococcus. With the enormous usage of penicillin there has been a steady climb within hospitals of the proportion of resistant staphylococci, and this is reflected in the number of resistant staphylococci isolated from out-patients. Table I shows the proportion of penicillin-resistant staphylococci which we have isolated from patients with septic lesions attending the out-patient department between 1949 and 1956. Patients attending other departments in the hospital were excluded and, whenever possible, swabs were taken at the first attendance or when the lesion was incised.

As opposed to penicillin, resistance to other antibiotics is the result of contact with the drug. Once acquired, resistance is permanent, and by cross-infection, these strains have multiplied to a serious level. Table II shows the results of tests done in our laboratory on staphylococci isolated from infections within the hospital in the last eighteen months. (Organisms from one ward with an epidemic have been excluded.)

TABLE I.—PATHOGENIC STAPHYLOCOCCI ISOLATED FROM OUT-PATIENTS

Date	Number of strains	Percentage resistant to penicillin
1949–50	261	6
1952	200	16
1954–55	200	21
1956	200	26

TABLE II.—ANTIBIOTIC SENSITIVITY OF STRAINS OF *Staph. pyogenes* ISOLATED DURING EIGHTEEN MONTHS FROM SEPSIS IN HOSPITAL IN-PATIENTS, AND THE PURCHASE OF ANTIBIOTICS IN THAT PERIOD AND THE PRECEDING FIFTEEN MONTHS

Sensitivity		Purchase of antibiotics (% of total) (by weight)	
731 strains	Percentage		Percentage
Resistant to penicillin	75	Penicillin	45
Resistant to tetracycline	23	Tetracyclines	35
130 strains			
Resistant to chloramphenicol	5	Chloramphenicol	1
Resistant to erythromycin	none	Erythromycin	1
		Streptomycin	18

So far, resistant strains have been dealt with by new antibiotics, and there are at the moment at least three promising new ones. Staphylococcal septicæmia is a possible exception to this generalization. This infection is sometimes accompanied by an endocarditis, and for the successful treatment of an endocarditis an antibiotic which kills, rather than one which only inhibits, bacterial growth is to be preferred. As yet we have no new antibiotic which can take the place of penicillin and streptomycin as killing agents, and one that could do so would be very welcome.

I would like here to discuss the way in which sensitivity tests are done. Nearly all those in common use determine if an antibiotic will inhibit the growth of an organism. There are several methods of finding this out. We have preferred one in which the sensitivity is determined in primary culture. One reason for choosing this method is that if a sensitivity report is delayed for three days it loses much of its practical value, and with the direct method a specimen can be received in the afternoon and a report sent the next morning. In cases of urgency, and if the infection is a heavy one, a good idea of the sensitivity may be obtained after as little as five hours' incubation. An additional advantage of this method is that it facilitates the recognition of infections due to mixtures of sensitive and resistant organisms.

Another way of looking at resistant organisms is to try to prevent their formation. For all antibiotics, the more they are used, the greater the risk of producing resistant strains, and conversely, with less use, fewer resistant strains are made. In support of this Table II shows purchases of antibiotics in two years and nine months together with the percentage of resistant strains of staphylococci isolated from in-patients.

There are two other aspects of staphylococcal infection I would like to consider. When I was adding up the staphylococci from in-patients, I made a separate record of those from infections of nurses (Table III). It showed what we have, unfortunately, known for some

TABLE III.—SENSITIVITY OF 64 STRAINS OF *Staph. pyogenes* FROM SEPTIC LESIONS OF NURSES

Sensitivity	Number of strains
Sensitive to penicillin and tetracycline	5
Resistant to penicillin, sensitive to tetracycline ..	57
Resistant to penicillin and tetracycline	2

time: that staphylococci isolated from septic lesions of nurses are likely to be resistant to penicillin. The most interesting observation was that only two nurses were infected with tetracycline-resistant staphylococci, although these organisms were not rare within the hospital. Many of our nurses are nasal carriers of strains of *Staph. pyogenes* resistant to penicillin but sensitive to tetracycline, and perhaps the tetracycline-sensitive strains can compete successfully with strains which are resistant.

One of the most alarming forms of staphylococcal infection is staphylococcal entero-colitis. This relatively new condition, which has to be differentiated from other causes of diarrhœa after operation, appears to be due to an invasion of the gut wall by staphylococci. Fig. 1 shows the bowel wall of a fatal case, the dark material just below the surface being composed of enormous numbers of staphylococci. Entero-colitis has been reported in patients treated with Terramycin, Aureomycin, tetracycline and penicillin and streptomycin used together. Why one patient and not another should develop it is not known, although the fact that nearly every reported case has followed the use of antibiotics which suppress bowel bacteria, suggests that these normal bacteria can suppress the growth of staphylococci or that when they are removed conditions become more suitable for staphylococci. In contrast with the broad spectrum antibiotics, penicillin is rapidly destroyed in the bowel, and, as far as I know, no case of entero-colitis has been reported after penicillin alone. We have seen some 30 cases of this new condition. Only one has died, on the third post-operative day, the others being arrested by treatment or being relatively mild infections.

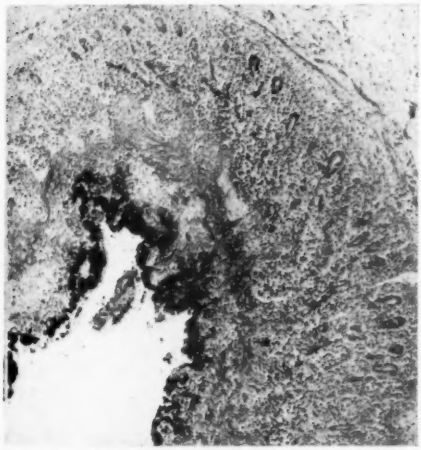

FIG. 1.—Section of jejunum showing superficial necrosis of mucosa. The dark-staining material on the mucosal surface consists of masses of staphylococci. ×50.

Photograph kindly lent by Dr. A. G. Stansfeld.

How to make the laboratory diagnosis is still uncertain. In our experience 30–40% of in-patients may carry pathogenic staphylococci in their stools, irrespective of treatment with antibiotics, and for this reason a culture may be misleading, as well as taking too long. So far, in our cases, we have relied on finding clusters of Gram-positive cocci in stained films of fæces, something we have only seen once in a large number of normal stools. There are reasons for suspecting that only a few types of staphylococci can cause enteritis, but even if this is so these types are now widespread, and in view of the rapidity with which patients may die, I think it is well worth while to make as a routine, stained films from patients with diarrhœa after broad spectrum antibiotics.

If the diagnosis is made in time, treatment is not difficult. It consists in stopping the offending antibiotic, restoring the fluid balance and removing the staphylococci with an antibiotic to which they are sensitive. At present this usually comes to the prescription of erythromycin, something which constitutes an additional reason for avoiding the use of this drug unless absolutely necessary. A new drug, or some new way of controlling the spread of staphylococci, might solve our problems rapidly. On the other hand, staphylococci have shown remarkable adaptability in the face of antibiotics, and have, so far, largely evaded attempts to control their spread, and I suspect that they will continue to present a major problem for some years to come.

The History of St. Peter's Hospital for Stone, London

By CUTHBERT E. DUKES, M.D., F.R.C.S.

ST. PETER'S HOSPITAL FOR STONE was founded in 1860, much later than most of the other special hospitals in London. The initial appeal for public support, dated March 12, 1860, declared that "there are in London six charitable Institutions for Idiots and Lunatics, nine for Lying-In Women, four for Women and Children, seven for Diseases of the Eye, two for Diseases of the Ear, four for Diseases of the Chest, two for Diseases of the Skin, five for Deformities, one for Cancer, one for Fistula, one for Fever, one Lock Hospital, and three Vaccine Institutions, yet there is no Hospital specially appropriated to the treatment of Stone". "Therefore", the appeal continued, "Some Noblemen and Gentlemen now propose to supply the existing want by founding an Hospital for the treatment of Patients labouring under Stone and other diseases of the urinary organs."

It was stated that one of the first objects of the proposed hospital would be to replace, as much as possible, existing operations of cutting for stone by newer methods designed for the crushing or dissolving of stones.

Another reason for establishing a special hospital for calculous disease of the urinary organs was provided by the fact that in the middle decades of the nineteenth century there had been a marked increase in the frequency of stone in England. According to the Registrar-General's reports, the number of deaths from stone and other diseases of the urinary organs had almost doubled in the ten years 1850–1860. It is difficult to explain this increase entirely on the grounds of more accurate diagnosis alone. Joly, J. S. (1940, *Med. Pr.*, **204**, 262) suggested that it might be an aftermath of the "hungry forties", just as the wave of calculous disease which swept over Central Europe in the 1920s was thought to be the result of privations during and after the First World War.

There are, of course, many different ætiological factors in the causation of calculous disease of the urinary organs. Some of these are of an individual or personal nature such as anatomical abnormalities, peculiarities in metabolism, urinary obstruction or infections; but if these are excluded the most obvious general factor responsible for calculous disease has always been a monotonous and unsatisfactory diet. It was formerly thought that stone in the kidney or bladder was due to over-indulgence in food. The exact opposite is the case. It is always commoner amongst poor people who are badly fed, and it declines in frequency when the diet is improved. The incidence of calculous disease has always been one of the most delicate indicators of dietary deficiency.

The Hospital for Stone, as it was first called, was opened in the autumn of 1860 at 42, Great Marylebone Street[1]. It was little more than an out-patient department as the building chosen was too small to accommodate more than a very few beds. The first

[1] The premises which in 1860 were No. 42, Great Marylebone Street were demolished in the early part of 1902. They were rebuilt (with No. 41) as shops and flats in 1903 and in 1904 an Order was made by the London County Council for the abolition of Great Marylebone Street and its incorporation with New Cavendish Street, with consequent renumbering. As the result of this, Nos. 41/42, Great Marylebone Street became No. 59, New Cavendish Street.

A further renumbering Order was made by the County Council in 1937, following the incorporation of Upper Marylebone Street, and as the result of this Order No. 59 became and is still known as No. 34, New Cavendish Street—three doors from the junction with Welbeck Street and occupied by Down Bros. and Mayer & Phelps Ltd., Surgical Instrument Makers.

Annual Report issued by the hospital tells us that the original intention had been to establish an in-patient department "in a healthy suburban situation", but this project fell to the ground from lack of funds. Three years later the committee secured the lease of 54, Berners Street[1], and in 1863 the hospital was moved there to a house large enough to accommodate 15 beds, though only about half of these were utilized at first in order to save expense.

When the hospital changed its address it also changed its name. As long as the institution had been in Great Marylebone Street it was called "The Hospital for Stone"; when it moved to Berners Street the name of "St. Peter's Hospital for Stone" was adopted. No reason or explanation for this change is to be found in the annual reports. In a short history of the Hospital published in 1940 Mr. Swift Joly pointed out that the custom of calling a hospital after some eminent saint has existed for several centuries and in many instances the result is appropriate and in good taste, but in a few it has been rather regrettable. He continues, "In no other instance does the name of the saint give an indication of the special work of the hospital."

During the first few years the Hospital for Stone met with even stronger opposition than had been experienced by the Eye Hospital at Moorfields which had been founded in the early years of the nineteenth century, by St. Mark's Hospital dating from 1835, by the Orthopædic Hospital in 1839, the Cancer Hospital (1851) and the Hospital for Sick Children (1852). This opposition found frequent expression in the *British Medical Journal*, which in its issue of June 16, 1860, launched a tirade against all the Special Hospitals of London. This was followed a few weeks later by a manifesto signed by many of the senior physicians and surgeons then on the staff of General Hospitals, beginning as follows: "We the undersigned are of opinion that much detriment to the public and to the medical profession arises from the modern practice of opening small institutions, under the name of hospitals, for particular forms of disease, in the treatment of which no other management, appliance or attention is required than is already supplied in the existing General Hospitals. . . . As an example that the evil referred to is increasing we regret to observe that an attempt is being made to set on foot a special hospital for the treatment of stone and diseases of the urinary organs. We desire to express our opinion that such an institution is especially unnecessary" (*Brit. med. J.*, 1860, ii, 582).

When St. Peter's moved to Berners Street the attack was renewed in another leading article in the *British Medical Journal* (1864, ii, 581), and in 1866 Mr. W. J. Coulson, a surgeon at St. Mary's Hospital, was called upon to resign his appointment at St. Mary's because he had accepted an appointment at this new special hospital (*Brit. med. J.*, 1866, ii, 703). But Mr. W. J. Coulson held the appointment of Surgeon to St. Peter's Hospital for twenty-five years, and at his death in 1890 the Committee recorded "that the present position of the hospital was due chiefly to his tact and affability which endeared him alike to the patients and his colleagues and all who had the privilege of working with him".

The many criticisms of Special Hospitals expressed in both the *British Medical Journal* and the *Lancet* during the early eighteen-sixties were not left unanswered, and the following extract from the Eighth Report of St. Peter's Hospital is a fair sample of the arguments in support of a Special hospital for Stone. This declared that "a leading journal has devoted several articles to prove that Special Hospitals are not only useless but injurious, but your Committee protest against sweeping assertions of this kind. Experience has abundantly proved that the only way of dealing successfully with the various types of disease that afflict humanity is to make each one the subject of particular study and care. It was with a view of alleviating the widespread suffering from Stone and other Urinary Diseases that St. Peter's Hospital was founded, and the friends of this Institution hope that their exertions may lead to as large an increase in the knowledge of these maladies, and to as great an improvement in their treatment as has been attained by the establishment of Special Hospitals for diseases of the Eye, the Chest, the Skin, the Throat, for Fever, for diseases of Women, and for Deformities" (Eighth Report of St. Peter's Hospital, 1868).

The accommodation in the Berners Street house was unsatisfactory and the work hampered by lack of funds until suddenly in 1873 the whole outlook was changed by an anonymous donation from a benefactor whose identity has never been divulged but whose generosity is commemorated by a brass plate in the hall of the present building. This tablet states the facts but gives no details.

On February 11, 1873, a stranger called at the hospital and presented a sealed packet to the Secretary. He demanded a receipt for it, at the same time stipulating that this packet should not be opened until he had left the building. The packet was found to

[1]Berners Street runs north to south from the Middlesex Hospital to Oxford Street, and No. 54 was situated on the west side about half-way down, but to-day you will look for it in vain.

Numbers 51, 52, 53, 55 and 56, Berners Street are occupied by the wallpaper merchants, Arthur Sanderson & Sons. No. 54 has ceased to exist.

contain ten thousand pounds—ten Bank of England notes for one thousand pounds each! The name of the donor was not disclosed, nor were any stipulations made as to the way in which the money should be spent.

The *British Medical Journal*, having lost the first round in its fight against St. Peter's, could not now resist the temptation of returning at once to the fray. Four days after the incident the Editor commented on it in the Editorial columns for February 15, 1873: "We understand that on Tuesday a gentleman called at St. Peter's Hospital for Stone, Berners Street, and left with the Secretary an anonymous donation of the sum of ten thousand pounds, in ten notes of one thousand pounds each. The munificence of the gift will attract deserved admiration. Wealth and munificence of this character involve, however, serious responsibilities; and on those who have at their command resources so extensive it must be considered an incumbent duty to watch over the useful administration of the funds which they provide. This institution is one . . . of the unnecessary special hospitals which constitute mischievous excrescences on our system of hospital charity; and the ill-advised munificence which endows it only tends to perpetuate an evil which might otherwise have been expected to die out with those who promoted it."

With this princely donation in hand the management committee began to look for better quarters and eventually found them in Henrietta Street, Covent Garden, to which address the hospital was moved in 1882. Here the newly built St. Peter's was formally opened by His Royal Highness Prince Leopold, Duke of Albany, on June 29, 1882. The total cost of the site and building was £13,923 and the furniture and incidental expenses £1,598, making £15,521 in all.

And now we come to the sequel of the story of the Anonymous Friend of St. Peter's, and one which gives it the authentic ring of the complete masterpiece.

In the year 1918 an old man was admitted to St. Peter's for prostatectomy. Before his operation he asked to see the Secretary, to whom he confided that he was the bearer of the envelope containing ten thousand pounds which had been left without any means of identification forty-five years previously. He explained that he was not the donor but that this "Friend of the Hospital" had died in the meantime. The name of the donor was confided to the Committee of Management. After a lengthy discussion in secret it was decided that since the donor had not revealed his identity during his lifetime and had apparently desired to remain anonymous, it would not be in accordance with his wishes to publish his name after his death. So no note of this discussion was made in the Minute book, and the name of this "Friend of the Hospital" is now lost for ever.

During the first forty years of its existence St. Peter's Hospital gradually built up a reputation for the successful treatment of stone in the bladder. The number of cases treated annually steadily increased and at the same time the death-rate after operation declined, attributable mainly to the substitution of litholapaxy for the former methods of operating, a procedure introduced by Bigelow of Boston in 1878. His operation consisted both in crushing the stone completely and evacuating the fragments from the bladder. As evidence of the change this brought about in the treatment of stone Swift Joly quotes a few figures from the statistics of St. Peter's Hospital. In the decade 1864–1873 the mortality following lithotrity (i.e. crushing the stone) was 15·25%. The average stay in hospital was about 100 days. In the decade 1915–1924 the mortality following litholapaxy (i.e. evacuation of the crushed stone) was 2·2%, and the patients only remained on an average five days in hospital. Bigelow's operation, combined with antiseptic methods, had brought about this striking change (Joly, J. S., 1929, Stone and Calculous Disease of the Urinary Organs". London, pp. 26, 27).

For the first forty years of its existence St. Peter's Hospital was true to its name and primarily renowned for the treatment of stone. When vacancies occurred on the staff preference was given to surgeons with special experience of calculous disease as shown by the fact that when in April 1896 the Medical Committee recommended that an additional Surgeon should be appointed to assist in the Out-patient Department the post was offered to Mr. P. J. Freyer (later Sir Peter Freyer) who, the report says, had "had considerable experience of calculous diseases in India".

Over four years later, in December 1900, Freyer performed his first suprapubic prostatectomy operation at the hospital. This operation revolutionized the general treatment of prostatic obstruction and also changed the emphasis of the surgical work of St. Peter's. There has been much controversy concerning the question whether or not Freyer was the first surgeon to carry out suprapubic prostatectomy successfully, but whatever views may be held about this no one will deny that by his teaching and example he effected a great improvement in the surgical treatment of prostatic obstruction, and greatly added to the renown of St. Peter's.

Freyer's operation held the field in Britain for twenty-five years. It was the operation of choice for the general surgeon, though few achieved results comparable with those

reported by Freyer. Many improvements were introduced a few years later by Sir John Thomson-Walker.

When St. Peter's Hospital was first built in Henrietta Street the ground floor at street level was rented to shops, but as the demand for beds increased the shops were displaced and the hospital came to occupy the whole site. The process of expansion and infiltration was a gradual one but by 1930 the entire building had been remodelled and a new out-patient department had been constructed on the ground floor, whilst the remainder of the available space had been used for an X-ray department and secretarial offices. There being no room for further expansion on the north side of Henrietta Street a house was acquired on the south side immediately opposite to the hospital, and here provision was made for the pathology laboratory, museum and Nurses' Home. This building, No. 10, Henrietta Street, is now the home of the Institute of Urology.

I think it is true to say that the Institute of Urology had its origin in a series of discussions between Sir Francis Fraser and Mr. Clifford Morson which took place early in 1946 at which it was agreed that steps should be taken first to unite St. Peter's Hospital with the neighbouring urological hospital, St. Paul's in Endell Street, after which the question of establishing an Institute of Urology could be considered. This proposal was submitted to the two hospitals concerned who agreed to commence organized instruction to post-graduate students early in 1947. Mr. Clifford Morson was subsequently appointed Director of Studies in the new Institute in May 1948.

All those of us who worked in the old voluntary hospitals before they were nationalized know how much these owed to the devoted services of members of the Committees of Management. Two names will long be remembered at St. Peter's. The first is that of Mr. F. A. Bevan who became Treasurer in 1866 and held this position until his death over forty years later. The second is that of Mr. Edwin Fox. He joined the Board of Management in 1879 and became chairman some twelve years later. He continued to hold this office until he died in 1933. To commemorate his long service to the hospital the paying ward which was opened in 1932 was named after him.

The History of St. Paul's Hospital, London

By A. R. C. Higham, F.R.C.S.

The tale I have to tell is not so exciting as that of St. Peter's; it lacks the highlights and some of the glory, but it is a story of humble beginnings, of difficulties overcome, of grave disappointments when success seemed at hand, of apparently inevitable ruin, and of final achievement that must warm the hearts of those still with us who knew the days of struggle.

A Mr. Felix Vinrace was the real father of the hospital: he interested a number of influential and philanthropic gentlemen, who met on May 27, 1897, "to consider the desirability of founding a hospital in Central London for the treatment of the many forms of skin and cognate diseases so prevalent in our midst".

A site was chosen, 13a Red Lion Square, and negotiations for the lease were concluded on March 24, 1898.

The large inscription in front "For Skin and Genito-Urinary Diseases" caused grave concern to certain residents in the Square; indeed, one, a Member of Parliament, was so incensed at the indecency of this inscription that he threatened legal proceedings. The Governors were unmoved.

The building was "replete with every accommodation befitting a modern hospital, embracing, obviously, its lighting throughout by electricity". Mr. Vinrace named the hospital "St. Paul's". He afterwards wrote "I spent some hundreds of pounds in putting the building into habitable repair—furnished it—and later on bought the lease which I now (1918) hold".

In view of what has since been written about the Patron Saint of our hospital, it is interesting to note that he said, in 1917—"The Committee have adopted one of the emblems of their Patron Saint as the Common Seal of the Hospital, as illustrated on the cover of this Report". This is the sword of St. Paul the Apostle.

The hospital opened its doors to its suppliants for relief on August 15, 1898, with Mr. Felix Vinrace, M.D., F.R.C.S., as Senior Honorary Surgeon, and Mr. Alfred Allport, M.R.C.S., as Assistant Honorary Surgeon (he was soon afterwards promoted to a "full surgeoncy"). There were 6 beds for in-patients.

The total Ordinary Income for the year ending December 31, 1898, was £76 19s. 6d. (there was a "loan" of £384 4s. 6d. Annual subscriptions amounted to £9 9s. 0d. There were donations of £32 16s. 0d., and the poor patients subscribed £34 4s. 6d. "Sale of Bottles" made 10s.

Expenses are interesting items: Provisions £3 7s. 7½d. Rates and taxes £6 13s. 0d. Nursing salaries £1 2s. 6d.

Throughout the early history of the hospital one is surprised to find what large sums were realized by the boxes in the hospital into which anonymous payments were made. In many years they amounted to more than the subscriptions of the well-to-do—and we had some of those, too: Horatio Bottomley gave us £10 0s. 0d., once.

In the first complete year's work there were 1,142 new cases, and 7,100 attendances. "As to the success of the treatment he could only say that of 16 operations performed during the past year (1891) not one had terminated fatally" (Annual Report, 1898–99).

I must interject here that I have seen the man who underwent the first operation in the hospital at Red Lion Square. He had had a wart on the penis treated then; I had to remove the whole organ for an extensive carcinoma at his second visit, sixty-three years later.

There is extant an interesting list of the places whence the patients came—London boroughs first, then the provinces. Among the list, but at the end, is one solitary entry from New York, U.S.A.

The South African War broke out and income dwindled, but enormous efforts were made—it was not unknown for the medical staff to have to put their hands into their pockets at the end of the week to find money to pay the orderlies, as one of them has told me. In 1904 donations amounted to £70 and patients' voluntary contributions to £441. In this year the Secretary defaulted to the tune of some £235 5s. 6d., and died in King's College Hospital, then, of course, quite near, while the Public Prosecutor was still considering *his* next step.

Debts now amounted to £2,037 11s. 10d. and assets to £114 5s. 1d. Nevertheless, patients continued to pour in, and the Surgical Staff was now four, with two anæsthetists.

By 1913 the income began to rise above expenditure, but there was a debt of £2,400. In-patients had had to be limited to 26 of the most urgent cases. The Insurance Act began to be a trouble: donations fell to £72 10s. 6d., while patients' voluntary contributions went up to £615 3s. 3d. Treatment with "606" was a great expense, X-rays were first mooted in 1913—it was thought that £150 would be required.

Then another war broke out, and the hospital had to be reorganized again. In 1916 St. Paul's became one of the 22 selected London Hospitals to give free secret treatment for V.D. In this year, 20 in-patients were treated for skin diseases and 606 for venereal diseases—this gives the first information of the incidence of the "cognate diseases" coyly mentioned in 1898; there were 20,000 attendances as out-patients, and new premises had to be found. An Extension Fund was opened, and in 1919 the present hospital site, then known as the British Lying-in Hospital was acquired for £15,000. This entailed a personal guarantee by the members of the Committee of Management—no small act of gallantry, which was soon to be tested. In 1921 the overdraft was £20,000, and all work on the new hospital had to be held up. At this moment F. N. Pickett endowed a laboratory, later to be known as the Pickett-Thomson Laboratory, which was built on the top floor of Endell Street. Dr. Robert Thomson began an association with the hospital which was only recently broken by his retirement. His brother David Thomson was the Director, and Sir Ronald Ross the President, of the laboratory, which was autonomous.

Finance continued to be the great difficulty, and the Hospital did not open up in Endell Street until 1923. It closed on Saturday, April 7, in Red Lion Square, and opened on Monday, April 9, at Endell Street "without friction".

In the first complete year at Endell Street out-patient attendances were 65,260 as against 20,168 in the previous complete year at Red Lion Square. It was obvious that the Medical Staff would have to be increased and the following appointments were made in 1924.

Claude H. Mills (Assistant Surgeon, 1914) and Graves Stoker were promoted Honorary Surgeons.

Kenneth Walker was made an Honorary Surgeon.

Sir Thomas Carey Evans, Winsbury White, and W. K. Irwin, Honorary Assistant Surgeons.

In 1926 the lift was installed, a Cystoscopy Room was equipped and opened, and post-graduate training in urology began.

That year saw a mortgage substituted for the system by which the members of the committee of management were individually responsible for the overdraft, and the medical staff was augmented by

Frank Kidd		
Jocelyn Swan	as Honorary	Consulting Surgeons
Nathan Mutch	,,	Physician
W. J. O'Donovan	,,	,, to the Skin Department
Frank Cook	,,	Gynæcologist

In 1927 the title of the Hospital was changed to "St. Paul's Hospital for Diseases (including Cancer) of the Genito-Urinary organs and Skin". This, after thirty years' activity, marked the change from the "cognate diseases" to Urology.

In this year the Ward was opened with 18 beds: an operating theatre was equipped and used (this is *still* in use) and an X-ray department was equipped at a cost of £2,000, the bulk subscribed through the exertions of the medical staff.

In this year also, Felix Vinrace died, leaving, as a final donation, the sum of £833 15s. 11d. to the Hospital—this was the money he had lent to the Hospital in its early days.

His recorded gifts to the hospital amount to nearly a thousand pounds: besides this he had persuaded many more than the few original "influential and philanthropic gentlemen" to give unsparingly of their time and treasure to set the Hospital on its feet.

He was born in 1858, was educated in Birmingham and at Queen's College, Galway; he studied medicine at University College and the London Hospital, qualifying as M.R.C.S. in 1879 aged 21. He became M.D. in 1881 and F.R.C.S. in 1886.

He was medical officer to the Hospital for Women in Soho, demonstrator of anatomy at the London Hospital, and had held posts as house surgeon, house physician and resident obstetrician at several Birmingham hospitals.

In 1887 he joined the Honorary Staff of the Birmingham Skin and Urinary Hospital, a post he held until 1919, being elected Consulting Surgeon in 1921. He must have spent a good deal of time in travel.

Between 1927 and 1930 the Honorary Staff was increased. Another gynæcologist, Alexander Galletly, a radiologist, G. R. Mather Cordiner, a cardiologist, T. Jenner Hoskin, and a surgeon in charge of the radium department, Stanford Cade, though it was not until the next year that £500 worth of radium was acquired.

In 1930 another great change took place. A separate department of venereal diseases was opened under the direction of Claude H. Mills, with Alfred Allport as his Assistant Director. The activities of the hospital and of this department have gone on side by side ever since, though they have been under separate management since 1942.

The next years were marked by steady development and the financial position gave less anxiety, though more hard work was required. In 1936 the hospital opened its own pathological laboratory.

In 1939 another reconstruction of the staff occurred, and three honorary assistant surgeons were appointed. They did not have time to arrange their out-patient days, let alone any operating sessions, before they were all in the R.A.M.C. and it was thought necessary to close the hospital for the great evacuation. However, before the year was out, it had to be reopened owing to popular demand, and it continued to work under the well-known difficulties with only one bad "near miss", in 1944, until the full reopening in 1946.

It was clear that great changes in the structure of the Hospital Services were imminent. The Governors entreated the other great genito-urinary hospitals to amalgamate with a view to building a centre of teaching and research—St. Peter's finally agreed, but All Saints remained outside, and so the Institute of Urology was originally based on St. Peter's and St. Paul's, which had amalgamated on May 9, 1948, without outside help.

I cannot conclude without paying a tribute to the original staff—men like Vinrace, Alfred Allport, who died in May 1949 and is commemorated in the ward of his name, Claude H. Mills, who taught me so much, Carey Evans, Winsbury-White and W. K. Irwin. These men not only worked in their own departments and did much of the day-to-day administration, but subscribed most liberally when funds were so vital, in the earlier days. Their recorded donations amount to over £8,500 and their unrecorded gifts must be very much more.

But, to us who remain, their greatest gift has been the example they left to us—we will not forget them. I wish to thank this Section for giving me an opportunity of making my sense of gratitude more widely known.

Section of General Practice

DISCUSSION ON CATARRH AND ITS TREATMENT

Dr. Harold Bloom:

Catarrh as a Family Illness

CATARRH is ubiquitous in the Western hemisphere. By long usage, the term has been applied both to the symptoms and to the exudates.

MORBIDITY IN CHILDREN

Enlargement of lymphoid tissue.—The constant, and often copious, mucopurulent discharges which occlude the nasal passages of certain "catarrhal" children must originate from large expanses of inflamed mucosa in the accessory sinuses.

Furthermore, the idea of "physiological enlargement of lymphoid tissue" is recognized to be a contradiction in terms. Any permanent enlargement of lymphoid tissue, whether subepithelial, or of tonsils, adenoids, nasal mucosa or cervical glands must be regarded as the result of inflammatory reaction to constant organismal invasion. This enlargement becomes evident in the pharynx after the first year of life, and its continued presence leads me to look for the source of the infection in the child's environment.

The common cold.—The common cold, or upper respiratory infection, is by far the most prevalent family illness known to us. It is highly infective and contagious, and is recognized by universal clinical and lay experience as a source of serious illness in young and old alike. The ubiquitous sequel to repeated infections is spoken of as chronic catarrh, which is constantly present in a large proportion of homes.

Now let us enquire into the effects upon the children of these repeated infections and of their aftermath.

Sources of infection in the home.—Douglas (1951*b*) found that, in all social classes, age or birth order, children are much more likely to suffer from respiratory infections when one or more of the other members of the family have frequent colds.

In another survey (1951*a*) he found that approximately 1 in 5 of children under 5 were admitted to hospital at least once. A small number went to hospital more than once. Readmissions occurred usually soon after the previous admission, and for the same cause, usually respiratory infection. These findings, if confirmed, suggest that the illness is the result of a source of constant infection or reinfection in the home.

The corollary to this situation is sometimes encountered. Children living in a home which harbours a chronic bronchitic repeatedly suffer severe respiratory infections. Soon after the death of the chronic invalid the children cease to be seriously ill.

We may infer from these surveys that there exist in the home two distinct sources of infection to children: (i) the intermittent colds, and (ii) a constantly present focus or foci. This last source is the individual with chronic catarrh.

THE CATARRHAL STATE

Catarrh in the adult.—The symptoms in the catarrhal adult, with his frequent and prolonged coughs and colds, stuffy nose and morning phlegm, are those of intermittent obstruction with retention and overflow in the upper respiratory tract. These symptoms have become part of the national heritage. Our patients, with their limited vocabularies, are unable to express themselves adequately. If the symptoms were brought to medical notice, the patients were often advised to ignore them (Ellis, 1954).

The signs invariably reveal the presence of long-standing and repeated inflammation in the respiratory tract. A brown pigmentation of the skin is often seen round the eyes outlining the orbits. The tongue is always coated, and often slimy. The pharynx and uvula are dusky, œdematous and often the seat of a granular hypertrophy of the subepithelial lymphoid tissue. Punctate hæmorrhages or dilated capillaries may be present

on the uvula, soft palate or tonsillar folds. Rivulets of mucopus, or even a frank cascade, may be seen, and sometimes mucopus wells up in the pharynx when the tongue is depressed.

In the nose the inferior turbinates are hypertrophied, œdematous and frequently obstruct the airway. Polypi may be present. The external auditory meatus is often the seat of a diffuse, indolent inflammatory process which sometimes reaches a focus in a meatal boil. The strictly healthy ear-drum is seldom seen in such families. It presents varying degrees of irregular thickening, retraction, scarring, plaque formation and often patchy œdema. No two drums show identical changes. Sometimes an indolent otitis media will produce a perforation and a heaping up of masses of unhealthy desquamation over the drum and meatus.

These signs are seen concurrently in the throat, nose and ears. They are the signs of chronic low-grade inflammation in the whole expanse of the respiratory tract. Somewhere within this a focus of chronic infection has developed and this may be demonstrated.

A radiological investigation in my practice confirmed the presence of this focus. During 1954, 22 out of 37 unselected catarrhal adults were found to have severe infection, hitherto undiscovered, in at least one paranasal cavity.

Catarrh in childhood and infancy.—Illingworth (1953), in assessing the health of the individual child, considers that the most important criteria of well-being are energy, happiness, freedom from infection and freedom from lassitude. In sharp contrast to this picture is the catarrhal child with his physical and mental lethargy. In between his attacks of illness he suffers from a condition of subclinical ill-health.

A familiar sign in the catarrhal child is a bluish shadowing round and under the eyes outlining the orbit. He toys with his food, drooping over table or desk and leaning on his elbows. He is round-shouldered, often has a lordosis with "winged" scapulæ, and the abdomen is frequently protuberant and tympanitic.

After the age of 1 year, when the effects of constant organismal infection are beginning to show macroscopic signs, physical examination reveals a picture similar to that seen in the adult. The tonsils and cervical glands are relatively much larger and the signs of fibrosis in the ear-drum and elsewhere are less advanced.

Catarrh in the baby.—The symptoms of infection of, and obstruction in, the upper respiratory passages in the baby are often dismissed as "snuffles". Snuffles in the newborn is described by Apley *et al.* (1954) as occurring in one in forty babies born in hospital. They found that the incidence rises steeply in the presence of a coryza infection among the nursing staff, and concluded that snuffles is an infection of unknown ætiology.

The symptomatology is similar to that of catarrhal infants and children. Its behaviour in the presence of "coryza" is similar to the familiar outbreaks of colds in the home. I believe, therefore, that snuffles is the earliest manifestation of the catarrhal state.

Sources of infection in the home.—Notwithstanding the assertion of Watson (1955) that the catarrhal state is a temporary condition, we see here clinical evidence of a permanent state of respiratory mucosal and lymphatic tissue reaction to constant organismal invasion. This reaction is abundant, prolonged and chronic, beginning as snuffles in the baby and progressing throughout life at varying levels of activity.

A focus of infection soon develops somewhere within the respiratory tract. These foci have been labelled chronic bronchitis or chronic otitis media, according to their position, and are well established by the time they are radiologically evident. The constant overflow into the pharynx from these foci is appreciated as catarrh.

These exudates constantly reinfect the pharynx and its lymphatic drainage.

In addition to this autogenous source of infection, there is the constant reaction to organismal invasion from other catarrhal foci in the environment. The catarrhal state thus behaves as a family infestation.

The acute exacerbations of inflammation, with retention and overflow, in this great area of respiratory mucosa are dismissed as "colds". The extensions of the colds are known as acute respiratory infections.

This thesis is supported by an investigation in my practice of the incidence of respiratory illnesses in the under-fives, and of the occurrence in their environment of chronic infection.

The Catarrhal Family

The observation that certain children appear to be more prone to illness than others led to the recognition of the catarrhal family, as distinct from the non-catarrhal family, which appeared to be analogous to the farm-worker's family mentioned by Douglas (1951).

The catarrhal family was defined as one in which a child, or children, suffered two or more attacks annually of acute upper respiratory, or pulmonary, infection, acute otitis media, or acute cervical adenitis, for which medical advice is sought. The definition is based upon observation or recorded knowledge of the family for at least two years.

Method of Investigation

All those families in my practice containing children born after December 31, 1949, were chosen. Children belonging to catarrhal families, according to the definition, were compared with the remainder. There were 107 catarrhal families with 136 children under 5, as against 20 non-catarrhal families with 25 children.

The incidence of acute respiratory illnesses in the children was recorded, together with the occurrence in their families of catarrh, chronic sinusitis, chronic bronchitis and chronic otitis media. A separate analysis was made for the presence in the family unit of the so-called "allergic" illnesses of hay-fever, migraine and asthma. Neither the severity nor the duration of the illnesses has been recorded.

Respiratory infections in children.—Table I shows that, in catarrhal families, there are four times more acute respiratory illnesses in the under-fives, than in non-catarrhal families.

Table I.—Incidence of Respiratory Infections in the Under-Fives

	Catarrhal families	Non-catarrhal families
Number of families	107	20
Number of under-fives	136	25
Total number of acute infections in under-fives	1,180	51
Number of child/years	408	69
Acute infections/child/year	2·9 (a)	0·7 (b)
Ratio of (a)/(b)	4·1/1	

Snuffles.—The analogy of snuffles to the respiratory infections was confirmed by this investigation. It was found that snuffles occurred four times more often in the babies of catarrhal than of non-catarrhal families.

The chronic respiratory illnesses.—A similar comparison showed that each of the chronic respiratory illnesses in the environment appears to cause more than four times as many episodes of respiratory illness in the children of catarrhal than of non-catarrhal families. Each of these chronic conditions may therefore be regarded as equivalent.

The "family" illnesses.—It was interesting and significant to find that each of the so-called allergic "family" illnesses appeared to cause four times more respiratory infections in the children of catarrhal than of non-catarrhal families. These conditions therefore appear to behave as infections of the same order as chronic bronchitis, and presumably as infections of the droplet type. Recent work by Brockbank (1955) and Russell (1955) supports this assumption.

Catarrh as a family illness.—This investigation showed that if there are two or more members of the family with catarrh, the under-fives suffer a disproportionate amount of illness (Fig. 1).

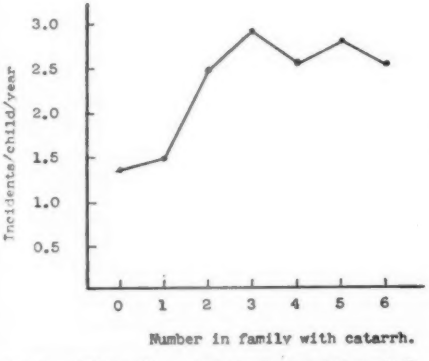

Fig. 1.—All families. Effect of catarrhal "units" in the home.

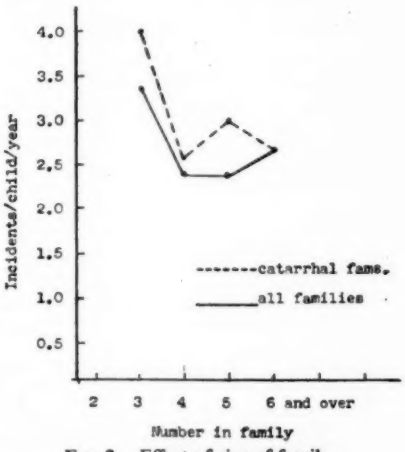

Fig. 2.—Effect of size of family.

The large family is no less healthy than the smaller one, so long as it contains no catarrhal "units". The only child appears to be a problem on his own, particularly in catarrhal families (Fig. 2).

Sources of infection in the home.—This investigation supports the clinical evidence that the chronic respiratory conditions, and the so-called "allergic" illnesses, behave as equivalent foci of droplet infection to children. Catarrh is the ubiquitous symptom of all these conditions, and appears as a family illness.

Discussion

I believe that one of the principal factors in the incidence and spread of the acute respiratory infections is the permanent slowing down, and ultimate partial paralysis, of ciliary action by the catarrhal exudates, and the consequent arrest of pathogenic organisms in them.

These catarrhal exudates are a medium highly favourable to the proliferation, and the spread, of the causal organisms of acute respiratory illnesses.

The total capacity of the air-spaces of the skull is stated to be 138 c.c. (Gray's Anatomy, 1955), or one cupful. In the upright position the overflow from these spaces is directed backwards into the nasopharynx. To this is added the overflow from the remainder of the respiratory tract. After stimulating salivation (Wright, 1952), the total mass is swallowed.

It would be well to consider the possible immediate and remote effects of the ingestion of this constant flow of mucopus, both in the acute and the chronic phases of the inflection.

Among the factors which aggravate the catarrhal state are atmospheric pollution, cold, sudden changes of temperature, humidity, fog, smog, tobacco smoke and damp housing conditions.

The emotional factor in catarrh cannot be ignored. Respiratory congestion resulting from emotional causes may precipitate a state of retention in which secondary organismal infection supervenes, producing the attack of asthma or sinusitis.

Within the limits of my practice, chronic otitis media, chronic bronchitis, migraine and asthma do not occur in non-catarrhal families. It is possible that our most catarrhal children grow up to become our chronic bronchitics and asthmatics. The approach to these conditions lies in the elimination of family catarrhal infestations.

Dr. Guy Daynes:

Treatment of Catarrh by Warmth at Night (Abridged)

Warmth in various forms has been accepted as a standard treatment for inflammatory conditions of the upper respiratory tract for many years. Why then are catarrhal patients allowed to sleep in bedrooms with icy blasts of fresh air blowing in through the open windows? Unthinking tradition must be the answer to this question; window-opening whatever the weather began as a preventive treatment for tuberculosis and its success led to its adoption as a health rule throughout this country. Our belief in the almost magical properties of fresh air has continued unshaken ever since!

This health habit is now challenged and the suggestion is made that *catarrhal patients benefit by shutting their windows at night!* Very many cases of "catarrh" originate from chronic virus infections in the upper respiratory tract and antibiotic therapy is useless against these viruses; therefore reliance must be made on Nature's own mechanism of leucocyte defence. If mucous membrane capillaries are contracted by cold air, there will

be a smaller blood flow and fewer leucocytes will reach the attacking viruses and therefore defence will be less efficient. If, on the other hand, the capillaries are dilated by warmth, more leucocytes will be able to join battle with the viruses, thereby improving the position. Any good that can be done by warmth will be completely neutralized by the use of vaso-constrictor nose drops and these should be reserved for purely allergic catarrh. Though such drops may temporarily prevent catarrh formation (just as cold air can), the viruses, if present, will be able to enter the mucous membrane cells relatively unopposed, and catarrh will be worse later.

Catarrhal patients ought to remain in warm rooms, the temperature of which should not fall below about 60° F. This will mean having a source of heat of some sort in the bedroom on cold nights, in addition to a closed, or nearly closed, window. Care must be taken to maintain some ventilation so that the room is not stuffy. The only difficulty in using this simple therapy lies in overcoming the patients' prejudices against it. If resistance is encountered, patients can be compared to a man who, having a bad "cold", sits wearing two overcoats on a frosty day in a room without heating and with the window wide open! He may insist that he is perfectly warm, but is he being sensible? Most patients will say that he is either mad or determined to get pneumonia, whereupon it can be pointed out that they are doing precisely the same thing each night when they tuck themselves up in bed, having thrown open the window wide. Logic will usually persuade them to shut their window and stay in the warm, if their catarrh is troublesome enough to justify such a supreme sacrifice!

Dr. H. C. Faulkner:

Displacement Therapy in Nasal Catarrh. Brief Interim Report on the Use of the Proetz Displacement Technique in General Practice

The Proetz technique has been fully described by Bedford Russell.[1]

The ætiology of chronic nasal congestion is multifactorial. Anatomical structure, sensitivity to inhalants, changes of temperature and humidity in the atmosphere, smoking, infections, both of the nose and sinuses and the teeth and alveolar margins, and stress and emotion all can play a part. Some would add the repeated use of vaso-constrictor sprays and drops to the list. Persistent rhinorrhœa, particularly in children, may be little more than inconvenient. The headache and general malaise arise when the ostia of the sinuses are blocked. Possibly the air in the sinuses is absorbed and produces a temporary vacuum, which alone produces a "sinus headache". The fact that retained secretion can cause headaches even if not manifestly secondarily infected can be demonstrated by the relief obtained by drainage.

Diagnosis is relatively simple. A bull's eye lantern and a head mirror make examination far easier. Dental abscess or alveolar osteitis should be excluded. I have recently seen a patient who had extensive investigations of her sinuses and innumerable treatments before the dental cause was found. The nasal mucosa typically loses its pale pink normal appearance and is œdematous and injected. Tenderness over the frontal and maxillary sinuses is less reliable, and its absence does not exclude the condition.

Bacteriology is seldom conclusive; antibiotics, surgery (except in the acute or chronic case with pus under tension), and desensitizing injections, have been disappointing. A change of climate is often more successful, but available to few patients.

The Proetz method, first described by Proetz in 1931, and popularized by Bedford Russell to a limited extent in this country, is extremely simple and worthy of a trial in general practice.

The first requirement is a spray with a fine nozzle and a sufficiently long tube to go far back in the nose. Neophryn shrinks the mucous membrane more efficiently than ephedrine. The only other requirement is a rubber bulb, with a removable glass nozzle which fits tightly in the nostril. The nose is sprayed with Neophryn. A few minutes later the patient lies on a couch with the head over the end, with the chin and external auditory meatus in vertical alignment. Two drachms of normal saline containing ½% ephedrine hydrochloride are introduced, 1 drachm in each nostril, the patient breathing through the mouth. The bulb is then compressed and fitted snugly into one nostril. The patient repeats "key, key" while the bulb is allowed to expand gently. If the ostia are patent this allows air to leave the sinuses and some of the solution to enter. This is repeated a few times.

Of some 30 cases of chronic nasal catarrh treated this year, I have kept separate records of 12. All have had relief, some dramatic. One did not return after the second treatment when some relief was admitted. The 2 who do their own treatments have had several attacks during the year, but still find the treatment effectively obtains rapid drainage.

[*December* 13, 1956]

DISCUSSION ON THE VISUAL PROBLEMS OF NIGHT DRIVING

Mr. L. H. Savin (King's College Hospital, London):

The subject of this discussion raises among others the following problems for the ophthalmologist:

(*a*) *The problem of dazzle*

When driving at night every motorist experiences difficulty from the dazzle of approaching headlights, especially if undimmed. Glare of this sort may be followed by a dangerous interval of defective dark adaptation before the eyes adequately recover vision. What is the best way to avoid this hiatus in visibility? Experienced night drivers will be found to adopt one of the following techniques:

(1) The commonest method is deliberately to keep from looking at the advancing headlights directly. The gaze is kept all the time on the near side of the road. This method is successful if the driver keeps his mind rigidly on his task.

(2) A second common method is to shut the left eye, opening it again after the glare has passed. It is an interesting fact that one eye may be dazzled independently without affecting the other. The efficacy of this method depends on how speedily the driver learns to suppress confusing after-images from the dazzled eye. Drivers say it takes a little time to learn the trick of suppression. They use this procedure particularly when the approaching light appears suddenly, as when the approaching car is coming unexpectedly round a bend in the road.

(3) An elaboration of the same technique is to keep the left eye open but to shade it. A commercial traveller attended a fancy dress party at which he wore a large and impressive false nose. On leaving the party he inadvertently still wore the nose, which he soon discovered was very useful for night driving. By a tilt of the head he could make the shadow of the false nose cover his left eye so that it was shielded from advancing headlights. Wearing a comic nose has its disadvantages if a driver is stopped at night by the police. He therefore later elaborated the idea by making a central vertical septum of blackened metal which he attached to the front of his distance glasses.

(4) *Dark glasses* can help against dazzle, but at the expense of lowering general visibility. This also applies to the gold-spattered anti-glare glasses formerly popular.

(5) *Polarization.*—It would be possible to eliminate dazzle to a large extent by polarizing light from headlights in one plane, while drivers wore glasses which polarized in a plane at right angles. The main trouble would be expense which at present rates would add about 33% to the cost of a headlamp. Another disadvantage is that the use of polarizing media in front of headlamps would greatly diminish the intensity of the light transmitted. To give adequate illumination of the road a much higher candle-power lamp would be necessary than that possessed by ordinary cars at the present time. This would increase the cost of motoring.

Perhaps this is the place to mention some other polarization phenomena. During the manufacture of laminated glass windscreens the layers of windscreen are made to undergo pressure. Inequalities of pressure may cause areas of windscreen subsequently to polarize transmitted light. Reflected light from a wet road is also partially polarized. Hence when travelling over a wet road at night with a dry windscreen it is often possible to note linear patterns on the windscreen where the polarization is contrary to the reflected road light. These lines are altered if moisture runs down the windscreen, because such moving fluid itself has a polarizing action. These phenomena materially affect visibility in driving.

The effect of dirt and dust on the windscreen and windows is worth study. Dust may produce diffraction effects such as small coloured haloes. Raindrops on windows or windscreen frequently produce distortion of the outside scene.

(6) *The deliberate use of dazzle.*—Most motorists have experienced unpleasant dazzle when the headlight of a car behind strikes the back window. The driving mirror is cut of action at once. A rear window blind is often fitted to cars for this reason, or alternatively a curved rear window glass which prevents the parallel rays of the following headlight from annoying by bringing them to an approximate focus. These devices prove only partially effective.

Police flying squads find dazzle from behind an effective weapon against car bandits. As they follow a fugitive car zig-zagging at top speed through side streets at night, the police try to follow close behind and concentrate their headlights upon the bandit car. They sound their gong, and the average car bandit in his excitement accelerates wildly. His faulty cornering and defective vision in the dazzle will cause him to crash unless he has displayed the foresight to steal a car with an efficient rear blind.

(*b*) *The Problems of Reflectors*

Properly adjusted reflectors on the backs of cars are a great help in making night driving safe. The ordinary reflectors depend on internally reflecting prisms and their "cube-corner-facets" reflect light efficiently if properly mounted. The regulations prescribe that such reflectors must be set at right angles to the baseline of the car both vertically and horizontally. These regulations are more honoured in the breach than the observance. Most car backs these days are curved posteriorly. If the reflectors are just screwed on flush with the posterior surface of the car, they are ineffective. Light from a following car is not reflected back to the driver of that car, but outwards and upwards. It is thus rendered useless.

Cat's eyes down the middle of the road are a great help to the night driver. Some roads have red reflectors down the near side and these have definitely proved their value. If these reflectors have colourless reflectors on their reverse side there is the advantage of a line of colourless reflections on the offside of the road too. This arrangement is being adopted by many authorities.

There is a good deal to be said for making cars carry colourless reflectors on their sides. This might be a help when cars reversed out of their front drives, or occasionally at cross roads.

The Times recently described a strip material known as "Scotchlight" which could be employed as a reflecting armband for pedestrians, or made into small portable reflecting danger-signs which could be stood in the road behind a car when the motorist was changing a tyre.

The hypermetropic eyes of animals, especially where the tapeta lucida are well developed, make excellent light reflectors at night, so that it is often possible to spot in this way a cat or dog in the road. The reflections from animal eyes can be seen from a much wider angle than the standard prismatic reflectors. A fortune awaits some manufacturer who will imitate animal eyes in the form of a glass lens inside a suitably curved reflecting base. Such ocelli could be in the form of buttons. One or two such button-ocelli sewn on the back of the overcoats worn by pedestrians would give a high degree of protection to the wearers.

It is quite remarkable what a high degree of protection is given even by such a simple object as a white scarf, which will greatly increase the visibility of its owner to the night-driving motorist.

Sometimes reflections from headlights may be of disadvantage to a motorist. If for instance there is mist or fog, the white light from the headlamp is reflected in diffuse fashion by the tiny fog particles. It is alleged that yellow headlights are not so liable to disperse reflection by the particles, and hence are better than white light.

In a foggy atmosphere there is commonly a clear layer of air below the fog on the surface of the ground. It is therefore advantageous for the foglight of a car to be down near the road surface, and also for the beam to diverge widely so as to illuminate the pavement edges before the car hits them.

(*c*) *Dark Adaptation and Night Driving*

Night driving brings up the following problems in which dark adaptation plays an important part:

(i) Motorists hate that uncomfortable period of twilight before lighting-up time. Shadows are falling, colour values are fading in accordance with the Purkinje phenomenon, and eyes have to peer to see an unilluminated cyclist or a pedestrian. There is still enough light from the Western sky to make headlights of minimal value.

It is at this stage that side and rear lights make such a difference. They act as indicators of the presence of vehicles, and also the careful driver can draw useful inferences. If, for example, the rear lights of the car in front swing out towards the crown of the road, the driver may well be overtaking a cyclist without lights, so precautions are taken accordingly.

The careful driver gives an oncoming car a little more clearance than its sidelights would suggest, because older makes of car often project laterally beyond the sidelight. Sidelights are meant as position indicators rather than as illumination to help the driver on his route. There would be a great deal to be said for making lighting-up times half an hour earlier.

Once headlights come into play other useful inferences may be made. If an approaching car suddenly accelerates the headlights lift suddenly because the weight of the car is flung on to its back wheels. If an approaching car seems to have its headlights constantly tilted upwards either the beams have not been properly adjusted to parallelism with the plane of the road, or alternatively the tyre pressures are down a bit and there is a heavy load on the back seat. If such a car brakes the beams will drop slightly.

(ii) A driver at a party may leave a brightly illuminated room and find himself very badly adapted to the surrounding darkness outside when the time comes to drive away. One has seen such a driver reverse his car in a car park straight into a car which seemed easily visible to a dark-adapted onlooker. A short time sitting in his car before starting would have allowed his eyes to become dark-adapted sufficiently to avoid the mishap.

(iii) A similar difficulty is often experienced when street lighting suddenly changes in intensity. Brightly illuminated streets are good in themselves, but they carry the penalty that a driver may suddenly run from a well-lit area into an island of comparative darkness. There is one such area just after passing the Houses of Parliament before reaching Millbank, where the bright lights are suddenly followed by inky blackness.

(iv) If one is unfortunate enough to get badly dazzled by a headlight, this problem of dark adaptation may become acute. It may even be necessary to give a slowing-down signal, run to the near side of the road, and stop.

(v) The driver with retinitis pigmentosa or similar pathological cause of night blindness does not seem a serious source of difficulty. Such a person usually finds it so difficult to drive at night that he is unlikely to be foolish enough to do so.

(d) Problems of Street Lighting

This is a fascinating subject for the illuminating engineer, who has to consider not only the intensity of illumination he desires but its cost. Monochromatic light from sodium or mercury vapour lamps is often chosen for its cheapness and efficiency in running. Such light is very irritating to many drivers owing to the gross distortion of the colour values of objects seen through its agency. Curiously enough other drivers allege that monochromatic light of this sort has a hypnotic effect. If they drive along a straight road illuminated by sodium vapour lamps they find themselves dropping off to sleep, conducive factors being the sense of unreality produced by the altered colour values, and the monotony of a long straight road stretching indefinitely ahead. Avoidance of this monotony can be achieved by planning the roads in gentle curves as found on many of the Continental Autobahnen.

Illuminating engineers aim to guide drivers by one of two methods. They aim for objects on roads to be seen by drivers either as darker silhouettes against a light background, or less usually as a light outline against the background of a dark road surface. The nature of the road surface thus affects visibility (Harris and Christie, 1951; Christie, 1954).

Away from well-illuminated roads, the beam of a headlight will give reasonable illumination where it impinges. Trouble arises from objects off the direct light of the beam, which may be visible only momentarily. The police lay very great stress in their handbooks on the degree of concentration and attention required for night driving. Harris and Christie (1954) have worked out that allowing for the number of vehicles on the road the chance of fatal accidents increases on average 1·88 times at night. They consider the reasons for this increased risk very largely visual.

(e) Visual Requirements for a Driving Licence

There is widespread doubt whether the simple recognition of the figures of a number plate at 25 yards as demanded for a driving licence is really adequate. A person may quite innocently state in his application for a driving licence that he can see such a number plate, and never realise that he has a constricted field from chronic glaucoma, or is night blind from retinitis pigmentosa. Ideally a motorist should have good visual acuity, a full peripheral field, good colour vision, good vision at night, and minimal heterophoria. Yet we all know drivers who have driven for years without accident with vision defective in one or other of these characters. It is difficult to steer a middle course between a "fuss pot" mentality and lazy *laissez faire*. The number of road casualties indeed has risen to horrifying proportions, but if every applicant for renewal of a driving licence required a visual test, who would undertake the enormous number of such tests necessary? There are certainly not enough ophthalmic surgeons or opticians.

My own solution would be the compromise one of including a better and more compre-

hensive visual examination in the driving test, and also compulsorily subjecting to a visual test all persons before the courts as the result of motor accidents, or for such motoring offences as dangerous driving, or driving without due care and attention. Disqualification should be automatic if reasonable visual acuity is absent and unattainable.

I wish to thank Dr. J. F. Fowler the physicist at King's College Hospital for his help with this paper, also Dr. W. May and Dr. P. Wright.

Mr. H. C. Weston (Institute of Ophthalmology, London):

The visual problems of night driving arise entirely from the peculiar and often abruptly changing luminous field of view, which determines both the momentary visual capacities of the driver and the apparent content—and, hence, the intelligibility of the continuously changing scene.

Both absolutely and relatively, the luminance values in the night field of view differ much from those of the day field. From those parts of the field having sub-liminal brightness no useful information can be received: it is as if there were blind areas in the somatic visual field. In other parts, small patches of brightness are substituted for—and must be interpreted as representing—what, in daylight, are much larger areas of different brightness, colour and contour. In yet other parts, new brightnesses are added, some aiding and some hindering the rapid development of perceptions which we hope will be valid for the journey moment by moment.

The distribution of brightness in the night scene may not be merely such that the way ahead is so difficult to discern that the driver is compelled to proceed slowly and warily. It may be actually misleading so that, although confident he has solved the visual problem of the vista, on closer approach the solution is found to be incorrect and an emergency operation is required to avoid calamity.

Inclement weather generally increases the visual stress in driving both by day and night, but its adverse effect is always greatest at night. Then, it still further impoverishes a field of view already emptied by darkness of many features which ordinarily give rise to helpful visual impressions, including those parafoveal streams on which judgments of speed and distance largely depend. But, unlike darkness itself, it does not simply fail to reveal but intrudes new and disrupting features into the field and distorts the appearance of others. Rain is the most usual though not, of course, the worst of inclement weather for night driving. It gives a streaky appearance to lighted road surfaces, and against such a background objects in the dark areas are difficult to see. From the driver's viewpoint the situation is still worse, because his rain-spotted or streaming screen is superimposed on the external scene, so that parts of this, particularly the lateral and foreground parts, are made more indistinct. One of the major problems confronting the street lighting and highway engineers is to devise a system of lighting and a road surface that, while meeting other important requirements, will yield a satisfactory road appearance in wet as well as in dry weather.

Driving a motored vehicle at any time calls for ceaseless vigilance. Yet, except for road transport drivers on night shift, driving at night is usually done by people who are already fatigued by their daytime activities. Fatigue is insidious in onset and momentary failures of attention, as well as misperceptions, are among its earliest manifestations. They occur before there is any awareness of fatigue, yet, at night, unflagging attention and perceptual agility are especially necessary in view of the relatively unfavourable presentation of the changing scene.

Unlike Argus who could see all with his hundred eyes, we have only two and their gaze has to be directed to and almost continuously kept within a portion of the scene ahead which has small angular dimensions. Except on traffic congested roads, attention has to be given to the road some hundreds of feet ahead of the vehicle, this sighting distance being varied, of course, according to the speed of driving. A common sighting distance at moderate speeds in built-up areas is one of about 300 feet and, at this distance, the whole width of the road, most of the objects of interest to the driver and most of the visible light sources occupy quite a small portion of the total visual field (Fig. 1). It may be easy to visualize how small this driver's fixation field is if I say that it can be covered by a couple of postage stamps viewed at the conventional reading distance of 33 cm.: its angular subtense is about 8 by 5 degrees. Two points should be noted: (*a*) there is less tendency by night than by day to relieve the ocular muscles of static fatigue by occasional quick glances beyond the lateral

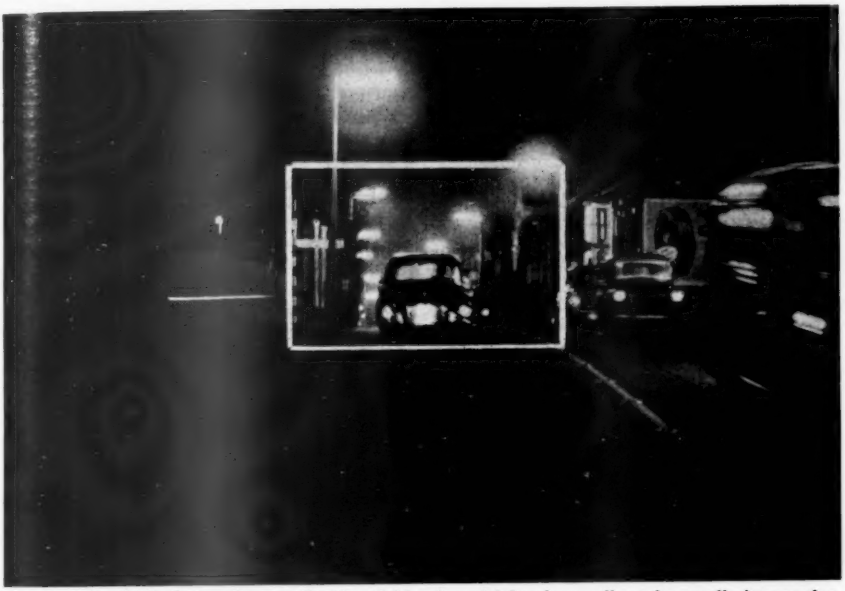

FIG. 1.—The field of attention, or fixation field, when driving is usually quite small: its angular subtense at the eye does not exceed about 8 × 5 degrees.

boundaries of this field—partly because it is more dangerous to do so, since the amount of information gained about what lies ahead is usually less than in daylight and is insufficient to give confidence that the fixity of the gaze may be relaxed even momentarily: (*b*) most of the street lamps—which are thousands of times brighter than any of the objects it is necessary to see—are crowded into this small field and so are imaged near the fovea where their glare effect is greatest. So far as the feeling of strain engendered by night-driving is referred to the region of the eyes it is almost certainly due to prolonged restriction of eye movements, in short, to staring—and partly due to restriction of blinking which always occurs during critical visual tasks. The more difficult the situation, e.g. when there is fog, the more sustained is the staring and the more acute the sense of strain.

Seeing while driving is obviously a paced task, like looking for faulty pieces among a stream of manufactured articles passing on a belt conveyor before an inspector. If the pace is too rapid and there are too many things in the display that should be observed before they pass out of sight, the perceptual load is too great, speed stress develops, and some of the objects which ought to be seen are inevitably overlooked. In the factory situation such oversights may not have disastrous consequences but they often have on the roads: accident rates are always higher in hours of natural darkness than in daylight hours, even on roads having good modern artificial lighting.

The artificial lighting of traffic routes is based on two principles. The first is to make the road surface, as seen in perspective by vehicle drivers, sufficiently bright for objects on the road ahead to be seen in silhouette, and the second is to do this without putting so much light from the street lamps into the eyes of drivers as to cause distraction, discomfort or any visual disability. To achieve a reasonably uniform and sufficiently high road brightness the lanterns must give an appropriate light output which they are designed to distribute in a particular way, such that the maximum beam intensity is at a fairly high angle from the downward vertical. The lanterns must also be mounted fairly high—25 feet is now general practice—and they must be appropriately spaced, usually from 100 to 150 feet apart. From the driver's point of view each lantern produces on a dry road surface a patch of relatively high brightness of T-shape, the patches from successive lanterns merging together so that the whole road ahead is fairly evenly brightened. Under these conditions, the visual problems of night driving are not very troublesome on uncongested roads, but this scheme of things is upset when the road is wet.

There are different types of lighting in use on traffic routes. For example, the lanterns are sometimes centrally suspended but more frequently they are staggered on either side.

If they are of what is called the cut-off type they need to be more closely spaced to obtain sufficient uniformity of road brightness but they have the advantage of giving less glare.

As to the kind of illuminant, six kinds are now in use—gas, incandescent tungsten, mercury discharge, colour-corrected mercury, sodium and fluorescent. It is impossible to compare these fairly on the road since they are used in installations which differ in other respects. But there is some evidence, that, given comparable installations, the monochromatic sodium light has some advantage as a driving light, and fluorescent light is also good.

If street lamps are so widely spaced—as they are in side roads—that there are extensive dark areas in the road, the detection of pedestrians and other unlighted objects which are in very poor contrast with such backgrounds requires the most intent looking and may be quite impossible. In side roads generally, and especially if one is unfamiliar with them, driving with car side-lamps alone not only makes the visual task of the driver often extremely difficult and trying, but can also be dangerous. Car side-lamps are intended to indicate the presence of the vehicle to other road users and not to provide a driving light. Unfortunately, pedestrians do not always realize that they can see a car by its side-lamps before the driver can see them.

Nothing is gained by using headlamps on stretches of main roads provided with the most up-to-date street lighting but, just because these stretches are so well lighted, in passing out of them to unlighted or dimly lighted roads dark-adaptation cannot occur quickly enough to ensure safe vision until an appreciable distance has been travelled. One way of overcoming the difficulty would be to scale down the street lighting gradually instead of changing or stopping it abruptly, but this is not likely to be done very generally. As things are now, dipped headlamps need to be switched on *before* leaving a well-lighted road. On unlighted roads when vehicles provide their own flarepath, objects on the road ahead are revealed by being made brighter than the surface which forms their background—the silhouette effect is reversed.

The headlights of oncoming vehicles make the road surface ahead of them appear brighter to an approaching driver than the surface illuminated by his own lamps and so objects in this part of the road are seen as they are in lighted streets. The lights of oncoming vehicles are sometimes very helpful in this way to a driver travelling in the opposite direction, as they may also be in revealing bends in the road. But the bugbear of night driving on unlighted roads is the frequent momentary exposure to the glare of undipped approaching

FIG. 2.—On this wet road the zebra crossing is almost invisible although it is floodlighted, but the flashing beacons indicate its presence.

headlamps and, unfortunately, to the more prolonged glare from maladjusted lamps even when they are dipped. To resist the phototropic effect of these bright light sources requires an effort of which we are often very conscious. At best, driving on unlighted roads nowadays involves frequent dipping of lights and consequent sudden shortening of seeing distances. Speed ought to be and often has to be reduced when these abrupt changes in visibility occur, but there are numerous occasions when during deceleration a considerable distance is travelled almost blindly. For a short period progression is more of an act of faith than a visually guided one, and this is also sometimes true when passing vehicles moving in the opposite direction on fairly narrow roads. A new problem of glare seems to be developing, due to the practice of equipping new cars with bigger and brighter stop and tail lamps. Stop lamps have to be bright enough to be unmistakably visible in daylight and this means that they may be unnecessarily and glaringly bright on dark roads by night. Something may have to be done in the future to make the brightness of such lamps adjustable for day and night driving.

Driving on empty unlighted roads provides most of the visual conditions favourable for the onset of the hypnotic state: an almost empty and monotonous visual field save for the relatively bright ribbon of road ahead to which the gaze is glued. There is something to be said then for having other vehicles on the road: their lights contribute to the visual stress of night driving but, at least, they help to keep the driver awake!

The visual problems of night driving have been added to in recent years by such innovations as roundabouts and zebra crossings. Signs giving advance warning of roundabouts are not always easy to see, nor are some other road signs. Roundabouts which are unlighted and not otherwise noticeably marked—as by a black and white curb or fence may not be seen in time to be negotiated when driving a car fairly fast on a gently curving or undulating road which is traffic free and apparently safe for fast travel. Accidents have shown the need for making roundabouts clearly visible and many are now suitably lighted or marked. Zebra crossings would often be difficult or impossible to see at night but for their beacons. As seen by the approaching driver, their distinctive white stripes are much foreshortened and the contrast between the white and black stripes may be insufficient to make the crossing conspicuous. When the road is wet, the contrast between the stripes may vanish completely—even if the crossing is floodlighted. Hence the beacons are very necessary indicators of the presence of a crossing (Fig. 2). Since, if steady, their lights could be overlooked, or their significance not realized—especially in localities where there are numerous other lights in the parafoveal field of view—it was a wise decision to make them conspicuous by flashing.

Mr. G. Grime (Road Research Laboratory, Department of Scientific and Industrial Research, Harmondsworth, Middlesex):

Road Illumination by Headlamps or Street Lamps

Consideration will be confined in this paper to problems of seeing with headlights and in street lighting.

The Importance of Improving Seeing at Night

An analysis of the figures for adult pedestrian casualties at night was made by Smeed (1953), in which he considered the changes in casualties which occurred when summertime was introduced and removed. In the hours that change from light to dark he found that casualties were approximately doubled, while in those that change from dark to light, casualties were halved. There is therefore scope for very considerable accident reduction by means of improved lighting.

Table I illustrates the relative importance of town and country as regards accidents. About twice as many serious and fatal night accidents occur in built-up as in non-built-up areas. This emphasizes the importance of making improvements in street lighting.

TABLE I.—ACCIDENTS IN DAYLIGHT AND DARKNESS, GREAT BRITAIN, 1954

Light conditions	Number of fatal and serious accidents: Built-up areas	Non-built-up areas
Daylight	25,500	12,200
Darkness	11,000	6,300

For street lighting there is reliable evidence of the improvement likely to result from re-lighting to modern standards. Tanner and Christie (1955) found that after re-lighting eight London streets to the upper limit of Group A lighting, there was an average reduction of 35% in personal-injury accidents.

Unfortunately, similar figures are not available for improvements in vehicle lighting.

The Physics of the Road Illumination Problem

For ease in driving at night, the lighting system, whether provided by street lighting or

by headlamps, must do two things: (1) enable objects on the road to be detected in good time, and (2) enable the driver to position his vehicle accurately in relation to the kerb and to other vehicles. The importance of the second requirement has not always been sufficiently realized when designing either vehicle or street lighting systems.

In satisfying these requirements, the lighting engineer is subject, for economic reasons, to a severe limitation in the amount of light which he has at his disposal. Brightness levels are therefore always extremely low compared with daylight; colour sensitivity is largely lost and so is the ability to resolve small details. The visibility of objects then depends mainly on the existence of a brightness contrast between the object as a whole and its background. Silhouette vision occurs when the object is the darker, and reversed silhouette vision when the object is the brighter. In seeing with vehicle headlights, the reversed silhouette is the more important; the object is illuminated by the headlamps and appears bright against a background of dark road surface. Objects are also seen, but less reliably, as dark silhouettes against road illuminated by the oncoming vehicle's headlights. In street lighting, where the object of the lighting engineer is to make the road surface as bright as possible, the dark silhouette is by far the more important (Fig. 1).

FIG. 1.—In lighted streets vision is mainly by silhouette. Occasionally the silhouette is reversed in the case of a pedestrian wearing light-coloured clothing.

Vehicle Lighting

In designing and using vehicle headlights the most difficult problem is to provide good seeing with minimum glare, when meeting another vehicle. The lamp designer's difficulties in attempting to solve this problem arise mainly from the smallness of the angular separation between the object, which needs the maximum illumination, and the oncoming driver's eye, at which, to avoid dazzle, illumination must be a minimum. Fig. 2 shows that, for a high visibility distance and a tolerable amount of glare at 400 feet, the intensity must drop rapidly between two points separated by only about 3 degrees. These remarks, of course, apply only to the "meeting beam" or dipped beam, used when another vehicle is approaching. The driving beam used on the open road presents no particular problem.

Lighting has to satisfy the two requirements of object detection and position keeping. Experimental techniques are now available for testing how well both requirements are met. The first gives a straightforward measurement of the distance at which a driver can recognize an object on the road in front of his vehicle when faced by another vehicle. Two test cars

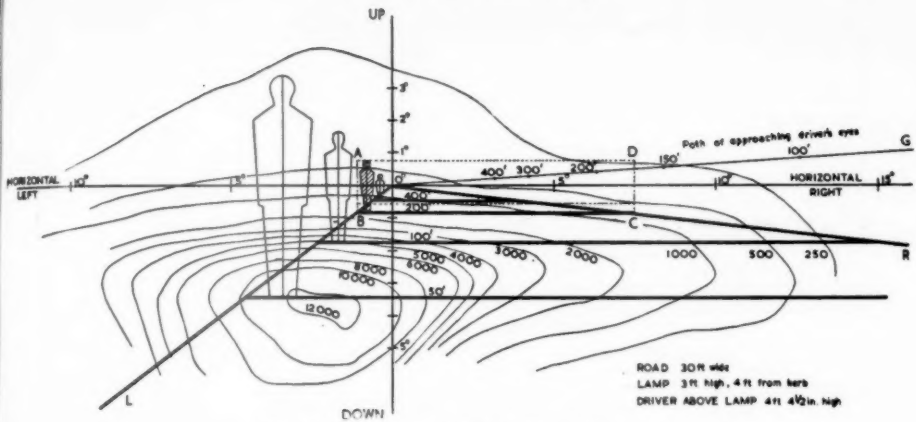

FIG. 2.—Geometry of headlighting problem.

are equipped with similar headlamps, properly aimed, and with apparatus for measuring distance. They start simultaneously from opposite ends of a test track, usually straight and level, along which objects of a dark colour are placed at intervals. The distances at which the driver sees the test objects are recorded by means of apparatus carried in the car. At the Road Research Laboratory a simplified form of this test has been used, in which one car remains stationary to provide the glare source, and the other carries the observer. Only one test object is used, placed near to the glare source but on the opposite side of the road. A further simplification was to employ beams of uniform intensity.

The results of many trials of this kind have been combined to produce the curves of Fig. 3 which enable the performance of a meeting beam to be determined when its light

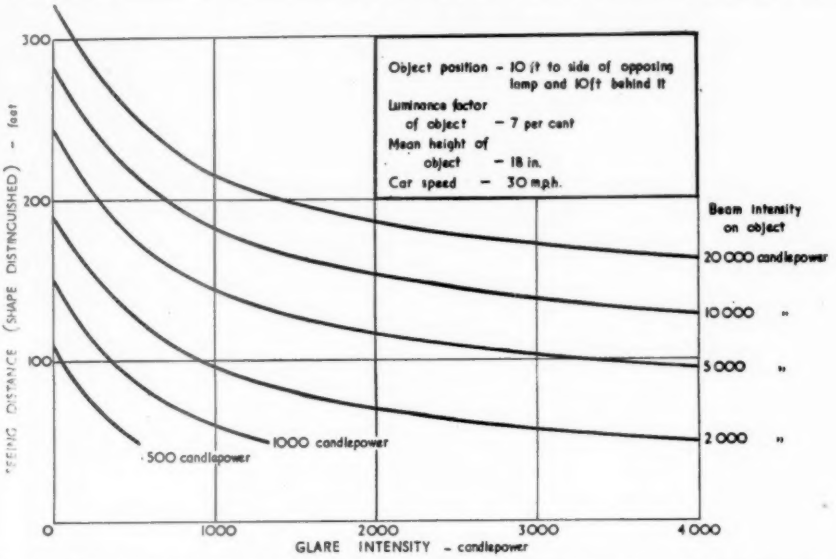

FIG. 3.—The relation between seeing distance, beam intensity directed at an object, and glare intensity.

output in different directions is known. Fig. 3 gives only a single figure for the minimum visibility distance in a particular meeting situation, but the calculations can readily be extended to cover other situations by making use of well-established physical laws relating the effects of glare to the angle between the glare source and the eye of the observer.

Tests of visibility distance alone are not sufficient to determine whether a meeting beam is satisfactory. A narrow pencil beam, for instance, may give a high visibility distance and yet be extremely unpleasant to drive behind because it throws little or no light on the road near the car. A test has therefore been developed which gives an indication of general performance and of the comfort of driving with a particular beam. The usual way of carrying out tests of this kind is to use the lamp in the ordinary course of driving on the public roads. A serious objection to this as a method of test is that it is not fair to judge a lamp by its performance when meeting anything but a similar lamp, and that this is not possible on the road. The objection can be overcome by making the assessment on a test track in such a way as to approximate to road conditions. The experiments (Grime, 1954) were made on a straight track about half a mile long, having man-size obstacles in two rows, one on each side of the track, and a line of smaller obstacles in the middle. The obstacles were an important feature of the procedure, since they compelled the drivers to concentrate on the task of driving. It was intended in this way to remove some of the artificiality of the tests. Two cars took part in the test, starting simultaneously from opposite ends of the track; each car carried the two sets of meeting beams to be compared. Eight runs were made using alternately one beam or the other, and the drivers then completed a questionnaire recording their preference. Runs were also made with the road surface wet. In most of the experiments, all the driver had to do was to make a direct comparison, and this helped greatly to increase the consistency of the results.

The main conclusions of these and other researches were:

(1) When the lamps are new and properly aimed most modern meeting beams provide similar visibility distances. Only small improvements in visibility distance are likely to result from further design changes.

(2) On British roads, however, headlamps are rarely aimed correctly, and many have deterioriated so that they emit no more than a feeble gleam of light. Many drivers are dazzled, and many are able to see only a very short distance. The aiming of lamps is so poor and the deterioration of lamps is so marked, that the most effective single step to increase visibility and reduce dazzle would be to bring up all headlamps to a similar state of efficiency and correct aim.

(3) Dazzle is determined not by the opposing glare intensity alone; it is decreased by the foreground illumination from the driver's own lamps. Thus, dazzle depends on one's own lights as well as on those of the oncoming car, and the driver of a car with feeble lights will be dazzled even by headlights in good condition and properly aimed.

(4) Broad beams, even of low intensity, are preferred to narrow ones, giving the driver greater confidence. The correctness of the design of the modern headlamp, in which a large proportion of light is spread widely over the road near the car, was confirmed.

An account of most of this work has been given by Harris (1954).

Street Lighting

The lighting engineer's problem in street lighting is to provide a well-illuminated background, usually the road, against which objects are seen in silhouette.

Each single street-lighting lantern produces one patch of light on the road. The art of street lighting is to combine these patches into a pattern of light on the road which satisfies the two requirements of object detection and position keeping. It was formerly thought that these objects could only be achieved by making the carriageway uniformly bright; we are now beginning to change our minds about this, and to think that certain kinds of non-uniformity are permissible. For example, a pattern of horizontal bands of light might reveal pedestrians and vehicles perfectly adequately and would therefore be acceptable, although it might not enable small animals to be seen at a distance.

The diverse types of street lighting are more fundamentally distinguished by differences in the distribution of light from the lanterns, than by more obvious differences such as colour of light and shape of unit. The two most dissimilar distributions are termed "cut-off" and "non-cut-off".

"*Non-cut-off*" *lighting.*—In this system most of the light is emitted almost horizontally up and down the road, and the patch of light from a single non-cut-off lantern is T-shaped, the tail of the T extending along the road towards the observer. The light is reflected from the road surface at small angles, generally less than 5 degrees. The whole pattern is obtained by combining the patches from individual lamps, and the result is a pattern of longitudinal patches.

The advantage of the non-cut-off system is its cheapness, since the lamp-posts may be widely spaced.

The disadvantages are, first, the high glare, especially when the road surface is a dark one and secondly, that it may become very poor and streaky when the road is wet, the long brilliant streaks producing particularly confusing patterns in these circumstances.

Cut-off installations.—As the name suggests, in cut-off lighting the tail of the patch is cut off and light is not allowed to be emitted near the horizontal. The individual patches run transversely across the road and there is very little glare.

The disadvantage is that a closer spacing of lamps is required than with non-cut-off lighting, and the installation is therefore more costly.

Intermediate systems.—Most modern British street lighting installations are compromises between the two extremes of cut-off and non-cut-off (Fig. 4).

FIG. 4.—Transitional lanterns intermediate between high- and medium-angle beam types.

The Road Surface

All these systems of street lighting have as their object to make the road surface bright as a background against which objects may be seen. The properties of the road surface are therefore of great importance in street lighting, and a substantial part of our work at the Road Research Laboratory on street lighting has been concerned with the study of the road surface as a reflector of light striking it at various angles (Christie, 1954). It is found that road surfaces act as "preferential diffusers", reflecting strongly, almost as in a mirror, at the tail of the light patch, but only very weakly and diffusely at the head of the patch near the lantern. The dominant factor in determining the reflection characteristics is the texture of the road surface, smooth surfaces producing long bright patches and rough ones shorter and less bright ones. Texture is particularly important in wet conditions, when a certain coarseness of texture is necessary in order to avoid the formation of a streaky and confusing pattern.

It has been shown, both theoretically (Christie, 1954) and practically, how important the road surface is in street lighting, and indeed it may be calculated that making the road surface lighter by a factor n has a greater effect on visibility than increasing the light output of the lanterns in the same ratio.

The road surface is perhaps of less importance in conditions where headlamps provide the lighting than in street lighting, but probably has a considerable influence on driving comfort. There is no general agreement, however, as to the relative merits of dark and

light road surfaces. Dark backgrounds should, in theory, enable objects on the road to be detected at greater distances than light ones; but from the few tests which have been made, the increase does not appear to be great. At the same time, there is indirect evidence that light-coloured diffusing surfaces are better than dark from the point of view of general comfort in driving, good position keeping, and reduction of dazzle. The evidence was obtained in the tests of general performance and comfort, where it was found that a broad beam, lighting up the road near the car, helped position keeping, and that a bright foreground reduced dazzle; a light-coloured road surface helps to produce a brighter foreground and to extend the width of the patch of light on the ground, and may therefore be expected to have the same effect as broadening the beam and increasing its intensity. More research is, however, required to define the optimum properties of the road surface.

This paper is presented by permission of the Director of Road Research.

Mr. Grime, in reply to the discussion, said that he would not like the question of polarized light to be dismissed as academic only. It was, of course, one of the very few solutions which offered an improvement in the ratio of the useful light to the glaring light put out to the other driver. It was true that with present windscreens there was a "chicken-wire" pattern due to the rotation of the plane of polarization through the windscreen and that had to be improved, or the other type of screen, the laminated type, which was very nearly as good as plain glass, must be used. The Road Research Laboratory had carried out quite a number of experiments on this and the main difficulties were still the psychological ones and the question of comfort in driving. When meeting another car one could undoubtedly see nearly twice as far with polarized lighting systems as with other types, but one had to look through a vizor which cut off half the light coming from the field of view and it was most unpleasant, since one wanted to look round it. It was possible to wear half-glasses in which the one half was polarized but that meant that one had to use two different positions for the head in driving, and one had to dip the head quite an appreciable amount because with the normal type of spectacle the lens was very close to the eye and the pupil subtended quite a large angle. Experiments were being made at the moment with mixed systems in which more light was put in the foreground than one could get with a polarized system in which a reasonable amount of power was used and it looked as though that kind of system might render a limited solution possible.

Basic Aspects of Mouth Development

By C. H. TONGE, T.D., M.B., B.S., B.D.S.

Reader in Oral Anatomy, University of Durham, King's College, Newcastle upon Tyne

THE mouth develops in unison with the other organs and tissues and cannot be considered without reference to the embryo as a whole. In embryonic and fœtal life, the visceral part of the head, including the facial structures and portions of the alimentary and respiratory systems, has a much slower rate of growth and differentiation than the neurocranial part. The primitive oral cavity or stomatodæum forms a portion of both the nasal and mouth cavities, the remainder arising from an inclusion of the primitive pharynx following the breakdown of the buccopharyngeal membrane. During the formation of the boundaries of the oral cavity, fusions occur which involve the fronto-nasal process, as well as the maxillary and mandibular processes of both sides. Failure of growth and union of these components in an orderly and mainly symmetrical manner results in malformations which may involve the face and the oral and nasal cavities in varying degree.

The aim of this study of mouth development is to consider the various phases of differentiation, with particular reference to their characteristic features and functional significance.

MATERIAL AND METHODS

Serial microscopic sections, cut sagittally, coronally and transversely, of 23 human embryos and 16 fœtuses were examined, together with representative wax plate reconstructions. Streeter (1942–1951) conceived the idea of dividing embryonic life into a series of horizons, demarcated as stages in development, then allotting each of the normal specimens of the Carnegie Institute Collection to its appropriate phase. The material used in this study has been graded in Streeter horizons and the ovulation age of each of the horizons indicated. In addition, the crown-rump measurement of each specimen is stated, and, where appropriate, reference is made to embryos described in the literature. The material examined ranges from the fourth week to the fifth month of intra-uterine life.

OBSERVATIONS

The 7-somite embryo of about 22 days' ovulation age, described by Payne (1925), emphasizes the development of the neurocranial part of the head and shows the presence of a large head fold. The stomatodæum is bounded by the developing fore-brain area above and the pericardial area below. The mandibular arches are at the sides and reach towards the pericardial area, whilst the processes which give origin to the lower jaw are not yet demonstrable. It is open ventrally, and dorsally the buccopharyngeal membrane with its ectodermal and endodermal layers separates the stomatodæum from the region which later forms the fore-gut.

The mandibular and hyoid arches are seen as surface elevations in embryos of 13–20 somites (horizon XI, ovulation age 23–25 days). They are also present in the 13–14-somite embryo described by Low (1908). The buccopharyngeal membrane is shown to be perforated in illustrations of a 20-somite embryo (Davis, 1923) establishing a free communication between the stomatodæum and the primitive fore-gut. The first three branchial arches are present in embryos of 21–29-somites (horizon XII, ovulation age 25–27 days), and partial fusion of the mandibular processes as they grow forwards may be observed in the older specimens of the group.

In a 5 mm. specimen (horizon XIII, ovulation age 27–29 days), the mandibular processes are meeting and fusing in the mid-line to form the floor of the stomatodæum, whilst the pericardial bar is gradually descending. In sections cut in the transverse plane, the embryo is seen to be lying completely within its amniotic sac; the fronto-nasal process, mandibular and hyoid visceral arches, as well as the dorsal surface of the embryo can be identified. The mandibular processes are separated ventrally and the first aortic arch artery can be seen traversing the mandibular arch tissue (Fig. 1).

In specimens of 5·6 mm. and 7 mm. (horizon XIV, ovulation age 28–30 days) the mandibular and hyoid arches are large and form prominent surface features. The maxillary process appears and the line of junction between the mandibular and maxillary processes forms a lateral wall for the mouth cavity defining the cheek. The fusion of the mandibular processes proceeds to completion forming the area of the lower jaw and the greater part of the floor of the mouth. The pattern of the tongue takes shape receiving elements from each of the first three visceral arches. The growth of the mandibular arches to form the lingual swellings creates a deep intermandibular sulcus in the mid-line region. The upper jaw and roof of the mouth is less well formed than the lower jaw and floor of the mouth. The maxillary processes are widely separated and the common bucco-nasal cavity is a cleftlike structure with a central diverticulum, Rathke's pouch arising from it (Fig. 2).

During the formation of the walls of the oral cavity, fusion of processes takes place. Union of the mandibular processes continues into later phases of development. The complete separation of the buccal and nasal cavities occurs last, by the union of the two palatal shelves of the maxillary processes with one another, and with the lower edge of the nasal septum. In Fig. 3 the mid-line fusion between the mandibular arches is seen. The surface epithelium consists of a single layer of flattened cells with well-marked heavily-staining nuclei. This clear-cut definition fades sharply in the region of contact of the two epithelial layers. The cells in the line of fusion are enlarged, pale and opaque near to the surface, whilst in the deeper areas, the definition between the adjacent cells is no longer clear, and many show abnormal and abortive mitosis. These phenomena suggest that the process of degeneration is slow. The mesenchymal cells are orientated with their long axes parallel to the epithelial cells in the line of fusion. As the epithelial cells disintegrate the mesenchymal cells re-orientate and bridge the gap, thus forming a continuous mass of tissue.

The formation of a face and the establishment of an upper jaw and primitive palate from the premaxillary process, as well as a primitive nasal cavity and bucco-nasal membranes between the nasal and oral cavities, characterize the four specimens, two 11 mm. and two 12 mm., allocated to horizons XV–XVII (ovulation age 31–36 days). During these phases continued growth occurs in the lower jaw and the mandibular division of the trigeminal nerve is larger than the maxillary division.

A 15 mm. specimen cut transversely, and two 15 mm. and a 16 mm. cut sagittally were placed in horizon XVIII (ovulation age 36–38 days). During this stage the nose and upper jaw are clearly discernible on the surface, the bucco-nasal membranes break down resulting in the formation of the primitive posterior choanæ. It is, also, the stage in which individual structures and the pattern of the musculature can be identified in the lower jaw region. Bartelmez and Evans (1926) showed that the cranial nerve complexes preceded mesenchymal tissue condensations in branchial arch fields. Fawcett (1905) showed that the mandibular nerve was the first structure to become differentiated in the lower jaw of man. Bardeen and Lewis (1901) as well as many others have identified pre-muscle condensations by tracing the main nerve supply to a region and following branches to them. In defining the individual muscle groups in the region of the mouth, similar techniques have been employed in this series. The lingual and inferior dental nerves can be seen, the former medial, the latter lateral, to the condensation which is the pre-cartilage phase of Meckel's cartilage. The nerve and artery to the mylohyoid can be traced and the mylohyoid and anterior belly of the digastric muscles demonstrated. It was not possible, however, to ascertain whether the mylohyoid and anterior belly of the digastric were formed from two separate condensations or arose from the same condensation. A wax reconstruction of one of the specimens examined at this stage and cut in the sagittal plane shows that the external surface of the face is established and the primary fusion lines completed. The floor of the mouth is formed and a primitive cheek mass identifiable. The primitive palate or premaxilla represented the only part of the true roof plate of the mouth. An early stage in the formation of the secondary palate could be seen as an inward growth of the palatal shelf of the maxillary processes. The site of Rathke's pouch was still visible. The tongue is well formed, its anterior two-thirds being more than ten times larger than the posterior one-third. The sulcus between the two parts of the tongue is clearly marked. Similarly, the vallecular fossa and epiglottis can be observed. The vestibule of the mouth has not yet formed since lip separation has not commenced. Microscopic examination of these specimens indicates that a considerable differentiation of the structures within the area of the floor of the mouth has taken place. The lingual nerve and submandibular ganglion, the mental, incisive and mylohyoid branches of the inferior dental nerve, as well as the hypoglossal and vagus nerves can be identified. Meckel's cartilage with its sheath and the cartilage of the second arch can be seen in their pre-cartilage stage. The condensations for the mylohyoid and anterior belly of the digastric muscles with the nerve to the mylohyoid between them are identifiable. Another zone of condensing mesenchyme marks the area in which the mandible will later ossify. The submandibular salivary gland has not commenced its differentiation

but the mesenchymal bed into which it grows can be seen (Fig. 4). The muscles of the floor of the mouth and tongue are made up of condensed areas of cells in which it is not possible to label myoblasts as distinct from fibroblasts. There is, however, some general tendency for elongation of the cells in one direction and some cells are already more elongated than others.

Four specimens, 18 mm., 18·5 mm., and two 19 mm. (horizon XIX, ovulation age 38–40 days), showed commencing osteoid deposition in the mandibular condensation and epithelial downgrowths for the parotid, sublingual and submandibular salivary glands.

Specimens of 20 mm. and 20·5 mm. (horizon XX, ovulation age 40–42 days) indicate that the maxillary process is becoming larger in size and depth. The palatal shelves of the maxillary processes are actively growing towards one another. The placodal area has grown inwards and the olfactory mucosa can be seen near to the roof of the nasal cavities. The nasal septum is growing downwards and a mesenchymal condensation is seen in it, preparatory to the formation of cartilage. The vomero-nasal organs are identifiable as invaginations from the surface of the nasal epithelium. The mouth cavity has breadth but negligible height, the area of the cheek is limited and the separation of the lip to give rise to the vestibular sulcus is just commencing. The parotid outgrowth is formed of a solid mass of epithelial cells which will later canalize and from which the parotid outgrowth lying upon the tissues of the first visceral arch is an early recognized structure of the cheek. The tongue still occupies a large part of the common bucco-nasal cavity and its musculature shows its

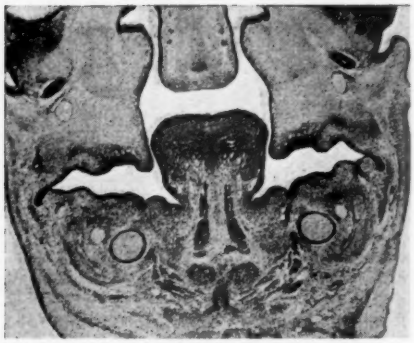

FIG. 5.—Coronal section of a 20·5 mm. human embryo. The common bucco-nasal cavity and the palatal shelves of the maxillary processes are seen. ×17.

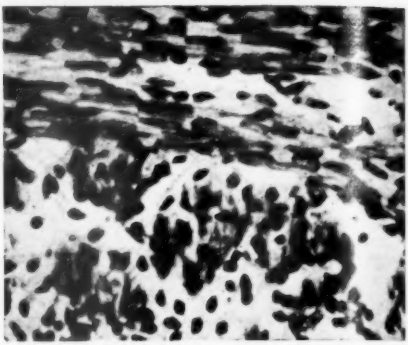

FIG. 6.—Sagittal section of a 28 mm. human embryo. The geniohyoid muscle is cut longitudinally and the mylohyoid transversely. ×517.

FIG. 7.—Coronal section of a 31·4 mm. human embryo passing through the buccal and nasal cavities and showing mid-line fusion of the palatal shelves of the maxillary processes. ×16.

component units. The framework of the oral floor is strengthened by Meckel's cartilages, the mandible has started to ossify on its lateral side and the inferior dental nerve is lying in a gutter formed by the bone (Fig. 5). The myoblast cells in the developing muscles can be recognized—elongating cells with as yet single nuclei.

Specimens of 24 mm., two 25 mm., 28 mm., 28·5 and 31·4 mm. (horizons XXI–XXIII, ovulation age 42–48 days), show a gradual differentiation of the muscle masses and the platysma can be seen sweeping over the superficial tissues of the neck and chest wall. In Fig. 6, the geniohyoid muscle is cut longitudinally and the mylohyoid transversely in the 28 mm. embryo cut in the sagittal plane. The muscle fibres of the geniohyoid are multinucleated. The long axis of the fibre is in the direct line from the muscle origin to its insertion. It would appear that this arrangement has resulted from the rapid growth in length of the myoblast accompanied by the rapid multiplication of the nuclei as a result of nuclear division by mitosis or amitotis without a similar division of the protoplasm. The transversely cut mylohyoid shows groups of muscle fibres with interspersed fibroblasts forming the connective tissue of the muscle. The 31·4 mm. embryo which was cut in the coronal plane shows the fusion of the palatal shelves of the maxillary processes taking place in the mid-line. The nasal septum has not yet reached the level of the fusing palatal shelves. Ossification is proceeding in both mandible and maxilla. The more anterior fibres of the mylohyoid are below the level of Meckel's cartilage supported on their submandibular surface by the digastric muscles. The posterior part of the mylohyoid passes progressively vertically from above Meckel's cartilage towards the mid-line raphe (Fig. 7).

The pattern of formation of the boundaries of the oral cavity is complete with the fusion of the maxillary processes and the completion of the secondary palate. The next process traced in fœtal specimens is one of ossification, thus completing the formation of a hard and soft palate. As muscle differentiation proceeds myofibrillæ become formed. These are situated peripherally and are clearly visible in specimens of 80 days' ovulation age, although striations are not present. In specimens of approximately 117 days, muscle fibres with well-marked cross striations could be observed in the tongue musculature and that of the floor of the mouth.

Discussion

An examination of the sequence of events occurring in the development of the mouth results in the conclusion that normal growth depends upon the right environment being available at the right time. Any factor, genetic, hormonal, nutritional, general or local, which disturbs the time environment balance will produce abnormal growth. The degree and site of malformation depends upon the stage of embryonic development reached prior to the application of the factor causing the imbalance. The formation of the branchial arches, their vascularization, the fusion of processes involved in facial development, the innervation of the mandibular and maxillary processes, the appearance of independent mesenchymal condensations, the differentiation of visceral arch cartilages, muscle masses and bone all take place as a closely integrated pattern. The first essential must be an adequate nutrition to maintain growth. When the embryo consists of a small number of cells, its nutritional demands are low and there is no necessity for a circulatory system. As growth proceeds, a circulatory mechanism becomes essential and the early endothelial heart tube and blood vessels develop. The first aortic arch artery passing through the mandibular arch tissue, present from an early somite stage, is seen in the 5 mm. embryo (Fig. 1). It is the first recognizable independent structure within the mandibular arch. The progressive development of these embryonic tissues must depend upon an adequate nutrition, which in turn requires an increasingly complex vascular pattern and circulatory mechanism to be present. The cinematographic studies of Patten and Kramer (1933) in a nine-somite embryo indicate that cardiac contraction commences as irregular fibrillations in the bulbo-ventricular area. The vessel itself is probably formed as a differentiation from mesenchyme prior to the establishment of a circulation. Its further development is associated with changes in the endothelium. These may occur as a result of the force of cardiac pulsations (Stockard, (1915*a*, *b*)). The position of the vessel within the embryo and the influence of neighbouring structures may also be causal factors (Hughes, 1943).

The material examined suggests that the fusion of the mandibular processes is mainly occurring between 27–29, plus or minus 1, days' ovulation age. The fusions of processes forming the face and the primitive palate development from the premaxilla occur during ovulation ages 31–36 days. The fusion of the palatal shelves of the maxillary processes observed to be taking place in specimens of ovulation age 46–52 days is probably completed by the end of the second month. For normal development, it is necessary for these fusion processes to occur at a definitive time in embryonic life. If the time of fusion is in any manner delayed, then non-union remains permanent and continued growth of the separated processes causes them to become even more widely separated. In this connexion the work of Woollam and Millen (1956) is of considerable interest. They review the experimental evidence of congenital malformations produced in animals subjected to diets deficient in vitamins and conclude that the embryo requires to store vitamins in order to avoid fœtal death or congenital malformation. They also stress the need for the potential mother to have a diet adequate in vitamins, in order to facilitate embryonic requirements in early pregnancy at a time prior to its usual diagnosis. Vitamin deficiency would appear, therefore, to provide an imbalance in the complex environment. An adequate supply of vitamins, although essential, may be only one of several factors which require to be present in order to obtain normal growth. The exact mode of action of vitamin deficiency in promoting embryonic disturbances seems to be unknown. It may result in alterations in the rate and timing of cellular divisions since members of the vitamin B group play an active part in cell metabolism.

Another important phase in the formation of the mouth, which was observed, was the differentiation of its structural elements. The differentiation of the submandibular salivary gland was found to be associated with a mesenchymal condensation, an arrangement similar to that found in relationship to the developing tooth (Tonge, 1953). The work of Grobstein (1953*a*, *b*) indicates the importance of the mesenchymal condensation in relation to the developing submandibular gland. He found that the submandibular epithelial tissue would differentiate typically, only when combined with submandibular mesenchyme.

Sucking and swallowing are functions well developed at birth in all mammals, and it seems likely that the structures necessary for these functions will be developed long before they are required. In considering prenatal muscle contraction it is well to remember that the more primitive mesenchymal cells and myoblasts seen in the earlier stages were capable of deformation in several directions. Their elongation committed them to deformation in one direction. The distinction is one of degree, at first the potentiality for irregular deformation of a part, later the capacity for a regular pattern of contraction—an essential before muscular contraction can occur. At 42 days' ovulation age myoblasts with single nuclei were seen in the tongue musculature, at 47 days multinucleated cells were present. Myofibrillæ were observed in specimens of about 80 days and it is generally conceded that the capacity to respond to direct irritation precedes myofibril formation. At 117 days there is

no difficulty in demonstrating muscle fibres with well-marked cross striations. The capacity for muscle contraction is now well developed and it seems likely that the contraction of muscles in swallowing may be possible at an earlier stage, an assessment of the musculature suggests about 11–12 weeks as a possible time. Thus, by the end of the third month the pattern of mouth formation is complete; it has commenced to function, and only additive growth and some remodelling occur.

ACKNOWLEDGMENT

I should like to record my thanks to Mr. C. J. Duncan, Director of the Department of Photography, for the photomicrographs, and Mr. D. Auld for technical assistance in the preparation of the histological material.

Marked Paget's Disease, Mainly of the Mandible, in a Woman

By WARREN HARVEY, M.R.C.S., L.R.C.P., F.D.S. R.C.S.Eng.

Introduction.—Paget's disease of the jaws is not common; for instance, the Oral Diagnosis Clinic in the School of Dentistry of the University of Pennsylvania had seen 3 cases in 50,000 admissions since 1935 (Burket, 1946). Novak and Burket (1944) reported that in 138 cases of generalized Paget's disease the maxilla was involved in 20 cases and the mandible in 3 cases. In 1945 Thoma, Howe and Wenig, from a review of the literature, found only 1 recorded case of monostotic Paget's disease of the mandible.

Case history.—A woman, aged 72, came from South America with the sole desire of seeking treatment to improve the appearance of her prominent jaw. She said that her teeth had always been difficult to extract and that her lower jaw started to get larger about six years ago; her hats were still the same size and her height had not changed. When her brother was 65 his jaw slowly increased in size.

On examination.—The teeth showed numerous carious cavities, but were firm and not spaced, and the gums were healthy.

On investigation.—X-rays showed no calcification in the suprarenals; the hands, long bones, vault and base of skull were normal. There was slight change in calcium density and the trabecular structure of the ilium and ischium near the right hip-joint was suggestive of very early Paget's disease. There was hypercementosis of the roots of the teeth in both jaws, and in the mandible there were areas of absorption and sclerosis.

The Wassermann reaction and Kahn test were negative. The serum alkaline phosphatase was 27·8 K.A. units (normal 3–13). The inorganic phosphorus was 2·4 mg.% (normal). The serum calcium was 10·2 mg.% (normal).

The radiographic evidence of concomitant osteoporosis and osteosclerosis, and the raised serum alkaline phosphatase were the significant features in the diagnosis.

The main interest of this case is that although there is such marked evidence of disease in the mandible, the rest of the body is only affected in the slightest degree, in the region of the right hip.

I am very grateful to Dr. H. W. A. Post for the X-rays and to Dr. J. H. O. Earle for the laboratory findings, and to Professor M. A. Rushton, who helped me in my dilemma as to treatment when he told me that inactivity might be masterly.

Fluoromar in Anæsthesia

By JOHN W. DUNDEE, M.D., F.F.A.R.C.S.

Lecturer in Anæsthesia, University of Liverpool

THERE have been many attempts made to improve on the original diethyl ether, but apart from Leake and Chen's introduction of the divinyl compound, there are no other ethers which have, as yet, received wide acceptance in anæsthesia. Most of the recent work on this subject is the result of systematic studies of various ethers by John C. Krantz, Jr., and his colleagues, from the University of Maryland. In 1946 they drew attention to methyl *n*-propyl ether (Krantz, *et al.*, 1946), which has sporadically received attention since, both in this country and in America. The following year they introduced ethyl vinyl ether (Krantz *et al.*, 1947), but its clinical use was not described until 1955 (Dornette and Orth, 1955; Sadove *et al.*, 1955).

Partially fluorinated ethers next attracted attention, and studies by Lu *et al.* (1953) suggested that tri-fluoroethyl-vinyl ether gave promise of being a useful anæsthetic agent. This drug, known as Fluoromar, was further investigated by Krantz *et al.* (1953) and clinical reports on its use have been published by Sadove *et al.* (1956), Gainza *et al.* (1956) and Dundee and Dripps (1957).

Table I shows the formula of Fluoromar in relation to other ethers in current use. The

TABLE I.—RELATIONSHIP OF TRIFLUOROETHYL – VINYL ETHER (FLUOROMAR) TO OTHER ETHERS USED IN ANÆSTHETIC PRACTICE

Formula	Ether
$CH_3-CH_2-O-CH_2-CH_3$	Diethyl
$CH_2=CH-O-CH=CH_2$	Divinyl (Vinesthene)
$CH_3-CH_2-O-CH=CH_2$	Ethyl–vinyl (Vinamar)
$CF_3-CH_2-O-CH=CH_2$	Trifluoro–ethyl–vinyl (Fluoromar)
$CH_3-O-CH_2-CH_2-CH_3$	Methyl *n*–propyl (Neothyl : Metropyl)

trifluorocarbon is very stable and the drug has none of the chemical properties of inorganic fluorides. There is no tendency for the vinyl grouping to hydrolyse and form acetaldehyde in contact with hot soda lime. Fluoromar is a clear colourless liquid, with a much less pungent smell than diethyl ether not unlike that of methyl *n*-propyl ether. Its oil/water solubility is 94 (3·2 for diethyl ether) and solubility in water 0·4 ml.%. The physical properties have been summarized by Sadove *et al.* (1956) and of these the inflammability range deserves special mention. While the low limit of inflammability of 4·0 vols.% is higher than that of the non-fluorinated isomer or diethyl ether, it is still well within the range used in clinical anæsthesia (3–8 vols%). The maximum spark energy for ignition is also higher than that of other ethers. In spite of the presence of a halogen in the formula, it has been shown that Fluoromar does not sensitize the heart to adrenaline. A hepatotoxic action might also be predicted from its physical properties but liver dysfunction is not any more marked after Fluoromar than after the use of other anæsthetics (Gainza *et al.*, 1956).

The course of induction of anæsthesia with Fluoromar in 287 hospitalized premedicated subjects, compared with similar cases receiving diethyl (575) or divinyl ether (115), at the same hospital by the same anæsthetists, is summarized in Table II. While the incidence of

TABLE II.—COMPARISON OF INDUCTION PERIOD IN PREMEDICATED HOSPITALIZED PATIENTS WITH THREE ETHERS

Ether	Diethyl	Divinyl	Trifluoroethyl vinyl
Incidence of smooth induction:			
(*a*) with N_2O-O_2	51%		65%
(*b*) following thiopentone	67%		75%
(*c*) open drop		65%	54%
Side effects during induction:			
(*a*) coughing	15%	4%	8%
(*b*) laryngospasm	3%	0%	4%
(*c*) excitement or muscular movement	17%	26%	11%
(*d*) excess salivation (adults only)	7%		2%
Adequate jaw relaxation during surgical anæsthesia	94%		73%

events attributable to irritant effects on the respiratory passages was lower with Fluoromar than with diethyl ether, the difference between the two drugs was not striking. The boiling point of 42·7° C. makes induction with the open drop technique difficult, as compared with divinyl ether. Of 28 cases in whom this was attempted with Fluoromar, induction was very prolonged in 7, whereas this only occurred in 4 out of 115 cases with divinyl ether. It was surprising to find that the incidence of good relaxation of the jaw muscles during surgical anæsthesia was not as good with Fluoromar as with diethyl ether. This may not be a specific effect of the drug but the result of its extremely rapid elimination, the few breaths of air taken during laryngoscopy or insertion of an airway having lightened the anæsthesia.

Once surgical anæsthesia was reached, there was a greater degree of flexibility with Fluoromar than with diethyl ether. Constant attention to the administration was necessary lest apnœa or too marked lightening should inadvertently occur. Guedel's classical planes of anæsthesia with diethyl ether were frequently inapplicable to Fluoromar. The sequence of events resembled the administration of cyclopropane in that, after morphine or pethidine as pre-operative medication, respiratory paralysis would frequently appear (Guedel, stage 3) before complete cessation of eyeball activity or loss of pharyngeal reflex (Guedel, stage 1). Electroencephalographic tracings during induction in 12 subjects showed changes similar to those described for diethyl ether. However, during established anæsthesia there was frequently some difficulty in assessing the depth from the EEG pattern. Surgical anæsthesia occurred at levels 2–3, deep anæsthesia at 4–5, while apnœa occurred between levels 5 and 7. Blood levels on 22 subjects (Dundee and Dripps, 1957), who only received atropine before induction, showed progressive depression of the central nervous system with increasing blood concentration of the drug. The range for surgical anæsthesia of 15–39 volumes per 100 ml. is similar to that found by Sadove *et al.* (1955).

Apart from effects secondary to tachypnœa, the action of Fluoromar on blood pressure and pulse-rate was similar to that of diethyl ether. However, the ease with which anæsthesia could be suddenly deepened gave the impression that hypotension was more common after Fluoromar, but the fall could be quickly reversed by lightening the depth of anæsthesia. Tachypnœa (to be discussed later), if of short duration, caused an increase in blood pressure, which could be reversed by the use of pethidine or controlled respiration. If tachypnœa was allowed to persist, the blood pressure fell after an hour or so to subnormal levels, and this sequence of events was invariably followed by moderate to severe post-operative hypotension. No disturbances in the electrocardiographic tracing were noted, save a displacement of the pacemaker during light anæsthesia, with return to normal as the depth was increased.

The respiratory rate during the use of Fluoromar is more rapid in patients who have not received morphine or pethidine before induction. In such subjects the incidence and degree of tachypnœa is about the same as for trichlorethylene. The respiratory rate increases with the duration and depth of anæsthesia, and at high rates the tidal volume is markedly depressed and respiratory acidosis occurs. As in the case of trichlorethylene, the intravenous injection of pethidine in 10–20 mg. doses abolished the tachypnœa and increased the tidal volume. Irrespective of the respiratory rate, Fluoromar was much more depressant on respiration than diethyl ether.

Abdominal relaxation was variable and was often as good as that produced by diethyl ether. Sometimes the inability to judge the depth of anæsthesia correctly led to poor operating conditions. The combination of Fluoromar with muscle relaxants was not studied in detail, but impressions suggest a synergism with the non-depolarizing drugs, such as exists with diethyl ether. Recovery from anæsthesia was always rapid and only 5 out of 280 cases, irrespective of the duration of anæsthesia, were not fully conscious within thirty minutes of the end of the operation.

The analgesic properties of Fluoromar were studied in patients undergoing operation and in volunteers. It was not as potent an analgesic as trichlorethylene, but after-effects did not

last as long. With the Cyprane inhaler at a constant setting, only eight to ten minutes' analgesia could be obtained, presumably because of cooling of the vapourizer. Recovery was not as prompt as after nitrous oxide—oxygen, and when this was used in conjunction with Fluoromar, there was difficulty in keeping the patient out of the second stage of anæsthesia. This combination proved very good for dental extractions and in premedicated hospitalized patients, but when tried in 52 unselected outpatients excessive salivation and nausea and vomiting were troublesome. Fluoromar did not prove as satisfactory as methyl *n*-propyl ether or trichlorethylene for this purpose.

A comparison of the properties of Fluoromar and its effects in man with those of other volatile agents is made in Table III. This does not reveal any outstanding advantage over

TABLE III.—COMPARISON OF SOME OF THE IMPORTANT PROPERTIES OF THE VOLATILE ANÆSTHETIC AGENTS

drugs already available in British anæsthetic practice. Had it been completely non-inflammable, it would have been very useful; and had it been less easy to produce apnœa and hypotension, it might have been the drug of choice for the inexperienced or occasional anæsthetist. As it stands there does not seem any point in introducing the drug into this country.

ACKNOWLEDGMENTS

My thanks are due to Dr. Robert D. Dripps of the University of Pennsylvania in conjunction with whom this work was carried out. Fluoromar was provided by Ohio Chemicals Ltd.

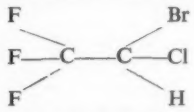
Some Observations on Fluothane



By R. BRYCE-SMITH, D.M., F.F.A. R.C.S.
First Assistant

and H. D. O'BRIEN, M.B., F.F.A. R.A.C.S.
Nuffield Dominion Clinical Assistant, Nuffield Department of Anæsthetics, University of Oxford

As our knowledge of Fluothane is still very incomplete we wish to avoid statements about its properties and behaviour which are too dogmatic, and to confine ourselves to what has been observed during the actual clinical administration of the drug in approximately 500 cases.

The investigation was begun in the middle of 1956 when Johnstone had already been using Fluothane for several months. We therefore had the advantage of knowing a little of what might be expected after reading a preliminary report which he submitted to Imperial Chemical Industries Ltd. who developed (Raventos, 1956; Raventos and Suckling, 1956) and manufactured the drug. The method of administration which he was using was also known, and through the medium of Sir Robert Macintosh who visited Johnstone at work, we received much practical advice. It is therefore obvious that Johnstone's experience is greater than ours, and any credit which may be due for the introduction of this drug into anæsthesia is his. On the other hand, if subsequent events prove that blame rather than credit is appropriate, we must accept our fair share in the knowledge that we may have furthered the popularity of this agent.

Fluothane is a clear, colourless, heavy liquid with a specific gravity of 1·86. It has a boiling point of 51° C., and thus volatilizes comparatively easily, giving off a vapour with a sweetish odour similar to that of chloroform. Chemically, it is a halogenated ethane which has the virtue of being non-inflammable and non-explosive.

It has therefore aroused the interest of the Medical Research Council Committee on Non-Explosive Anæsthetics who are independently carrying out an extensive investigation.

The first object was to administer Fluothane by the simplest means to determine the effectiveness of known concentrations of vapour, and in doing this to avoid, as far as possible, the influence of other anæsthetic drugs. Initially, therefore, we employed the open drop method of administration, and also an E.M.O. ether inhaler (Epstein and Macintosh, 1956) modified and calibrated for Fluothane. With the exception of volunteers and about 20 patients, all received some combination of premedicant drugs. In addition, the majority of our patients were induced with a preliminary injection of thiopentone.

It appeared that 1% Fluothane vapour in air was the weakest concentration capable of producing unconsciousness in an unpremedicated healthy adult. Even the prolonged inhalation of 0·5% Fluothane in these circumstances failed to cause loss of consciousness, nor indeed, any worth-while degree of analgesia. Concentrations of 2% Fluothane in air produced satisfactory surgical anæsthesia in most cases, although the degree of relaxation obtained depended to a large extent on the respiratory efforts of the patient (if these were not assisted) and, hence, the influence of other depressant drugs. Rarely was it necessary to exceed a concentration of 2%, although 3% was employed on occasions in robust subjects or where extreme degrees of relaxation were necessary.

Induction was usually rapid, smooth, and free from unpleasant subjective sensations for the patient. Coughing and breath holding were rare, and an excitement stage unusual. The preliminary injection of thiopentone seemed to reduce the incidence of restlessness and helped to provide a smoother induction. Thus, quite apart from considerations for the comfort of the patient, a "sleep dose" of thiopentone became routine before most administrations.

During the course of every anæsthetic we came to expect several characteristic features: flushing of the skin which became warm and dry; suffusion of the conjunctival vessels; and dilatation of the superficial veins of the limbs which became prominent. This occurred within a few minutes of starting the administration and was more marked than might have been expected with other forms of anæsthesia. The masseter muscles relaxed early and with depression of the pharyngeal reflexes an oral airway or a laryngoscope could be introduced. At this time, stimulation of the cords would result in closing of the glottis, possibly a cough, but not laryngeal spasm.

There was a fall in blood pressure within the first five minutes, usually accompanied by a reduction in pulse-rate. It has been suggested that Fluothane is a sympathetic-ganglion blocking agent, and the almost typical fall in blood pressure, together with the general appearance of the patient would support this view, although this has not been proved pharmacologically. In a high proportion of cases there was a fall in the minute volume accompanied by a compensatory rise in the respiratory rate. But in some volunteers, very slow rates were seen. This appears to be an individual variation which is not predictable and for which we can offer no satisfactory explanation.

After stopping the administration, consciousness returned quickly unless pre-operative medication had been heavy. We were impressed by the speed with which volunteers recovered their mental alertness, although a physical sensation of lassitude persisted for several minutes. During this time, diplopia was noticed and, not uncommonly, a marked

dryness of the mouth. On recovery, patients usually felt well and there was a minimum of nausea and vomiting. However, since there was no residual analgesia, the pain of an operation was soon felt and this effect was, of course, most marked in children who received a barbiturate for premedication. Not unnaturally this painful stimulation disturbs the patient and may cause restlessness. As soon as an analgesic was given, the restlessness ceased and emergence from anæsthesia became peaceful.

From this broad pattern of anæsthesia under Fluothane, certain features demand further attention.

Effect on the Respiratory System

As a rule, the depth of respiration decreased and the rate increased during the course of an anæsthetic. This was apparent clinically, and was often sufficient to cause cyanosis unless respiration was assisted, or oxygen added to an inspired mixture of Fluothane and air. Measurements of minute volumes were made by allowing the inspired vapour to be drawn through a spirometer, and were found to be surprisingly small. In both volunteers and patients recordings were obtained of less than 2 litres per minute after only five minutes' inhalation of 1% Fluothane in air. Such extreme degrees of depression were unusual, but it soon became obvious that an increase in the respiratory rate, even in the presence of an apparently adequate minute volume, could result in an insufficient tidal exchange.

Recently, we have attempted to reproduce Johnstone's technique of giving nitrous oxide, oxygen and Fluothane from a Boyle machine, but substituting the specially calibrated E.M.O. inhaler for the trilene bottle. The concentration of oxygen was never allowed to fall below 25%, and no cyanosis was seen in patients who received this mixture. The pattern of depressed minute volume and increased respiratory rate still persisted, and, in both groups, the effect of premedication was obvious, and confirmed our earlier opinion (Bryce-Smith and O'Brien, 1956) that light premedication with atropine alone, or pethidine 50 mg. and atropine, is preferable to the more usual mixtures containing morphine or Omnopon (*see* Table I). The response of the body to Fluothane vapour needs more careful study, and since it must be assumed that carbon dioxide retention is occurring under these respiratory conditions, a study of carbon dioxide levels is needed.

Table I.—The Effect of Light and Heavy Premedication on Minute Volume

All recordings were made after five minutes' inhalation, and demonstrate the higher proportion of low minute volumes in those patients who received Omnopon and scopolamine for premedication. There is an apparent difference between the Fluothane/air and the Fluothane/nitrous oxide/oxygen series which is difficult to explain.

Minute Volumes

	Premedication	
1% Fluothane/air	Pethidine 50 mg. Atropine 1/100 gr.	Omnopon 1/3 gr. Scopolamine 1/150 gr.
⩾ 6 litres/min.	28%	24%
3·1–5·9 litres/min.	52% } 24 cases	42% } 38 cases
⩽ 3·0 litres/min.	16%	34%
1% Fluothane, N_2O, O_2		
⩾ 6 litres/min.	23%	9%
3·1–5·9 litres/min.	37% } 30 cases	27% } 33 cases
⩽ 3·0 litres/min.	40%	62%

Under Fluothane/air anæsthesia, respiration is usually smooth, quiet and regular. The vapour is not irritating to the respiratory tract and respiration can usually be controlled with the greatest of ease at light levels of anæsthesia.

In experimental work on dogs, and in patients who received Fluothane/air only, periods of apnœa lasting for one to two minutes sometimes occurred during induction. These were never seen after induction with thiopentone, nor have they been apparent in patients who received the thiopentone, nitrous oxide, oxygen, and Fluothane mixture. This apnœa did not appear to be related to the concentration of vapour administered, and was not a response to a high concentration which might have caused laryngeal spasm. Inflation could still be performed with ease, and spontaneous respiration usually re-started after applying a painful stimulus.

Effect on the Cardiovascular System

The effect of Fluothane on the rate and rhythm of the heart has already been the subject of an intensive electrocardiographic study (Johnstone, 1956). We have detected no cardiac arrhythmias during Fluothane anæsthesia, but bradycardia occurred almost routinely. Even the administration of clinical doses of adrenaline (up to 0·5 mg.) caused no more than a temporary and brief increase in the pulse-rate.

Falls in blood pressure were common, and the degree of hypotension seemed to be related to the concentration of Fluothane vapour. In very few cases, however, were these falls of an alarming extent, and even when they did occur the general condition of the patient remained surprisingly good. Indeed, from the warm dry skin, and the strong pulse which could be felt at any of the classical points for palpation, it was hard to believe that any fall in blood pressure had occurred.

The blood pressure and pulse-rate tended to follow each other closely, and a rise in pulse-rate was nearly always followed by a rise in blood pressure. Thus we have come to place more reliance on atropine as the antidote to hypotension than on such agents as methyl amphetamine and ephedrine.

There was little to choose between the effect of Fluothane/air, and Fluothane, nitrous oxide, and oxygen on the blood pressure. The maximum and average falls of blood pressure in both groups were comparable, although the average fall with the higher concentrations of Fluothane (1·5–2·0%) was slightly greater in the Fluothane/air series (Table II).

TABLE II.—THE EFFECT OF DIFFERENT CONCENTRATIONS OF FLUOTHANE ON THE BLOOD PRESSURE

The average fall under 1% Fluothane is not alarming, but becomes appreciable with 1·5% and 2%. In a few instances, there was a rise in blood pressure (listed under minimum fall), and with 1% Fluothane, a reasonable number of cases showed no fall at all.

	Blood Pressure Falls (mm.Hg systolic)		
	Fluothane/N_2O/O_2		
	1%	1·5%	2%
No. of cases	28	8	6
Max. fall	75 (from 140)	100 (from 160)	70 (from 140)
Min. fall	+30	+10	10
Average fall	15	29	27
No. with no fall, or a rise in B.P.	11	3	1
	Fluothane/air		
No. of cases	42	12	16
Max. fall	70 (from 140)	75 (from 180)	75 (from 180)
Min. fall	+10	+10	5
Average fall	21	39	36
No. with no fall, or a rise in B.P.	10	1	0

All patients received thiopentone 0·25 gram for induction.

THE USE OF MUSCLE RELAXANTS WITH FLUOTHANE

Succinylcholine chloride has been administered to 101 patients under Fluothane anæsthesia. The effects appeared to be identical to those seen when this muscle relaxant is used with other anæsthetic agents.

43 patients have received gallamine triethiodide and in some there have been slight falls in blood pressure. However, the extent of these falls has been no more than might be expected with Fluothane by itself. In at least half of the cases, there was, in fact, a slight rise in blood pressure, coinciding with the rise in pulse-rate which is characteristic of gallamine.

d-tubocurarine chloride has been administered to 35 patients, but here the effect on the cardiovascular system tended to be more dramatic than with gallamine triethiodide. Falls in blood pressure were more common, and frequently more profound, but provided the concentration of Fluothane administered did not exceed 1%, there has been no cause for serious alarm.

We are of the opinion that the non-depolarizing muscle relaxants should be used cautiously in conjunction with Fluothane. In particular, there is a risk of serious hypotension when *d*-tubocurarine is administered in the presence of bradycardia. We must warn most strongly against the injudicious use of neostigmine. We believe that a preliminary injection of atropine should be made at least five minutes before the neostigmine is administered, and that the dose should be of the order of 1/75–1/50 grain. Neostigmine is best given in divided doses, never more than 1 mg. at a time, and the total dose not exceeding 2·5 mg. With less cautious dosage there may be a calamitous slowing of the pulse-rate.

These reactions to gallamine, *d*-tubocurarine, neostigmine and atropine are interesting, and when considered in relation to the appearance of the patient, the bradycardia, and the hypotension under Fluothane alone, suggest that this drug must exert some influence on the sympathetic nervous system. Since there is evidence that this does not occur at the ganglia, then it may well be that the action is more peripheral.

Miscellaneous Observations

Diplopia and dryness of the mouth have already been mentioned as not unusual features during the immediate recovery period. In addition, bouts of shivering lasting for five to ten minutes have been seen before consciousness has fully returned. The shivering appeared to be aggravated by any stimulation of the patient, but was seen less commonly when nitrous oxide, oxygen and Fluothane was used than Fluothane/air.

Unfortunately, the administration of Fluothane demands a very careful control of the concentration of vapour. Thus, most existing anæsthetic apparatus in its present form is unsuitable for the administration of the drug. The difficulty is further increased by the knowledge that Fluothane, in the presence of moisture, can attack tin and aluminium. Considerable difficulty was experienced before the E.M.O. inhaler could be modified for use with Fluothane without undergoing corrosion and, in consequence, jamming of moving parts.

Conclusion

It is too early yet to pass judgment on Fluothane, but we believe that this agent merits a place in the anæsthetist's armamentarium. Non-inflammability, ease of administration, flexibility, smooth and rapid induction, quick recovery with a minimum of after-effects, and a bloodless surgical field, are advantages which cannot be dismissed lightly. On the other hand, depressed respiration, hypotension and bradycardia have sinister implications unless they are controllable and reversible. Further, they may be fatal unless recognized. Other disadvantages undoubtedly exist of which we have little or no knowledge, and until the investigations of the Committee of the Medical Research Council and others have been completed, the use of Fluothane should be limited and cautious.

While we think that Fluothane is an improvement on ethyl chloride either as a sole anæsthetic or as an induction agent to ether, and by virtue of its flexibility could replace trichlorethylene in a nitrous oxide/oxygen sequence, to mention but two possibilities, we would be unwilling to make widespread recommendations for its use at present. It would be regrettable if such a promising drug acquired a bad reputation early on, due to ignorance of its properties and of the correct method of usage.

Dr. M. Johnstone: I have now administered Fluothane to over 1,200 patients, using the technique already described (Johnstone, 1956). With the 1% (approx.) vapour concentration the induction, maintenance, and recovery from anæsthesia have been delightfully smooth in each patient. Spontaneous respiration has persisted in all patients and significant degrees of respiratory depression have been uncommon, presumably because I do not use morphine or its analogues as premedicants. Increased respiratory rates are common during Fluothane anæsthesia but seldom of a degree requiring an adjustment of the technique.

Muscular relaxation has been adequate in all cases except in a proportion of the laparotomies; it has not yet been attempted to obtain further relaxation in the latter by increasing the Fluothane concentration. Roughly speaking, Fluothane 1·5% provides about 80% of the relaxation needed for an upper abdominal operation; the remaining 20% of the relaxation, required only during the initial exploration and the final closure of the peritoneal cavity, can be obtained with small doses of suxamethonium (30 mg. to 50 mg. intravenously). Longer-acting relaxants, particularly of the competitive type are not required and are probably contra-indicated for the reasons already mentioned (Johnstone, 1956).

As far as I can tell, disturbances of cardiac rhythm are practically non-existent during Fluothane anæsthesia in efficiently ventilated and adequately atropinized patients. Small hæmostatic doses of adrenaline (up to 20 c.c. of a 1/150,000 solution of adrenaline hydrochloride injected subcutaneously) have failed to cause any disturbance of cardiac rhythm in adults anæsthetized with Fluothane. I have observed a multifocal ventricular tachycardia following the filling of a congested bladder with about 400 c.c. of a 1/100,000 solution of adrenaline hydrochloride during a cystoscopic examination of a patient under Fluothane anæsthesia; the arrhythmia was abolished immediately by the insufflation of ether vapour and recovery was uneventful. The hypotensive effect of Fluothane is minimal with the 1% vapour concentration required for the maintenance of anæsthesia, provided atropine is given in adequate doses, the blood volume is maintained within reasonably normal limits, and postural influences are controlled.

Post-operative nausea and vomiting have been absent in over 95% of my patients after Fluothane

anæsthesia. On one point I am certain: the overall picture of the post-operative condition of the patients has been incomparably better than after any other anæsthetic technique I have ever used. An outstanding feature has been the complete absence of the shock syndrome after surgery under Fluothane anæsthesia. At the moment it is not possible to explain this effect but I feel certain it is related to the unusual pharmacological effects of Fluothane on the autonomic nervous system (Raventos, 1956), effects which are fundamentally different from those of any other volatile anæsthetic agent.

RAVENTOS, J. (1956) *Brit. J. Pharmacol.*, **11**, 394.

Dr. B. W. Peckett: Mr. Bernard Johnson and I have been giving a clinical trial to Fluothane at the Middlesex Hospital for the last three months. We have now anæsthetized nearly two hundred patients with a thiopentone, nitrous oxide, oxygen, Fluothane sequence using a Boyle's apparatus with Fluothane in the trilene bottle (1–2% Fluothane concentration was used).

Our impressions have been very favourable. It is easy and non-irritant to administer. Relaxation of the jaw occurs early, allowing insertion of the airway almost immediately. Relaxation is good and can be potentiated by the addition of any of the common relaxants. *d*-Tubocurarine chloride and Fluothane together generally cause hypotension, which is rarely severe. It appears to be safe with small quantities of adrenaline injected subcutaneously, but this requires further investigation.

Its worst feature is the often occurring, rapid, shallow respiration with marked falls in minute volume, but respiration can and should be assisted under these circumstances. It is very easy to control respiration completely.

Vomiting is mild following Fluothane, but it does occur.

We feel that Fluothane deserves a prolonged clinical trial and may well prove the best agent to use in the presence of diathermy, particularly for short procedures requiring moderately deep anæsthesia; and for operations where bleeding may be a great inconvenience to the surgeon, such as plastic operations, radical mastectomies, thyroidectomies and many E.N.T. operations.

Dr. H. J. Brennan: I have seen an alarming degree of bradycardia and hypotension in two healthy male adults premedicated with papaveretum and hyoscine—a condition immediately corrected by the intravenous injection of atropine sulphate. Hyoscine does not provide sufficient cardiac protection against Fluothane, and I regard adequate premedication with atropine as essential.

Dr. T. Cecil Gray: Fluothane appears to possess every property we consider bad in an anæsthetic drug: Tachypnœa combined with reduction in tidal volume, hypotension and sensitization of the heart to adrenaline are all extremely undesirable effects which the speakers have assured us are produced by this drug, and yet, to a man, they still regard it as a valuable agent!

It is probable that the facts that it is non-explosive, non-inflammatory and produces rapid induction and recovery of anæsthesia will give it a small niche in anæsthetic practice but I find it difficult to conceive that it will replace any of the agents at present at our disposal.

The whole trend of anæsthesia is to avoid the blunderbuss type of anæsthetic agent and to use drugs with as few side actions as possible, in order to achieve specific ends such as relaxation and hypotension. I hope that this is a principle that will not be easily abandoned.

Dr. L. Rendell-Baker: Though I agree that Fluothane opens a new and interesting avenue for research, I feel that the great frequency with which it produces bradycardia and hypotension often combined with marked diminution of the patient's tidal exchange hardly marks it as an ideal anæsthetic agent. The incidence of nausea and vomiting with Fluothane has certainly not been less than is commonly experienced following other agents such as trichloroethylene, for example. With some of the cases, vomiting has been troublesome.

[*October* 26, 1956]

Some Clinical Aspects of Developmental Anomalies of the Female Genito-urinary Tract

PRESIDENT'S ADDRESS

By R. A. BREWS, M.D., M.S., F.R.C.S., F.R.C.O.G.

THIS address is based upon case records for the past sixty years and autopsy reports for the past forty years at the London Hospital.

Gynatresia with cryptomenorrhœa	83 cases
Incomplete vaginal septa	17 cases
Duplication of genital tract without cryptomenorrhœa:	
Symmetrical	32 cases
Asymmetrical	12 cases
Other abnormalities of the genital tract	16 cases
Selected anomalies of the urinary tract	5 cases
Found at autopsy	35 reports
	200

In addition to commenting upon these 200 cases from the London Hospital, others are referred to which have come under my care in different hospitals during the recent half of this period.

GYNATRESIA WITH CRYPTOMENORRHŒA

83 cases of cryptomenorrhœa resulting from a developmental obstruction distal to menstruating endometrium are included in the series and in Table I they are grouped into clinical types:

TABLE I.

Occluding membrane at the vaginal orifice	
Hæmatocolpos. Simple 54, Double 1	55
Hæmatocolpos (H-C) and hæmatotrachelos (H-T)	1
H-C, H-T and hæmometra (H-M)	3
H-C, H-T, H-M and hæmatosalpinx (H-S)	3
Occlusion at a higher level	
In the vagina: vault H-C ±H-T, H-M and H-S	2
In the cervix: H-T ±H-M and H-S	5
Unilateral occlusion in a double genital tract	
In the vagina: vault H-C ±H-T, H-M and H-S	7
In the cervix: H-T ±H-M and H-S	1
In the corpus: H-M ±H-S (menstruating accessory horn)	6
(*Infection of retained menstrual debris*—5)	83

The clinical features of simple hæmatocolpos are well known but a few points have emerged from a study of the 54 cases in this series. About half of them came under medical care because of difficulty in micturition or retention of urine. One-third complained of pain, in many cases typical of dysmenorrhœa, but in others, of a dull aching character above the pubes or in the sacro-perineal region, aggravated by sitting or by defæcation and probably due to vaginal distension. The remainder presented in a variety of ways, complaining of such things as abdominal swelling, hæmorrhoids, or anxiety because of delayed onset of periods, and initial diagnosis included appendicitis and ruptured ectopic pregnancy. One girl of 15 years fell on her perineum and, in doing so, ruptured a hæmatocolpos with embarrassing social consequences. The age incidence ranged from 12 to 24 years and 5 of these girls were 18 or older.

The only case of double hæmatocolpos was admitted under Dr. A. H. N. Lewers in 1907. A single girl of 17 years, she had never menstruated and a sudden retention of urine brought her to hospital. After catheterization a tense abdomino-pelvic swelling reached from the perineum to just above the pubes. The external genitalia were well developed but there was no vaginal opening. Dissection at its normal site opened two vaginæ distended with tarry fluid and with a separate cervix at each vault.

In 7 further cases of hæmatocolpos due to a low vaginal atresia distension also involved the genital passages at a higher level. In 1 the cervix alone was affected (hæmatotrachelos), in 3 the uterine body as well (hæmometra) and in the remaining 3 cases the fallopian tubes were also affected (hæmatosalpinx). Involvement of the uterus and fallopian tubes does not depend upon the size of the hæmatocolpos. The largest in the series contained 4½ pints and in this case the uterus and fallopian tubes were not distended, whereas both were grossly distended in an instance where the hæmatocolpos contained only 10 oz. Apart from palpable enlargement of the tubes, there must be many cases where a little fluid finds its way back along them to the peritoneal cavity. Again, dilatation may have involved the upper genital tract even when symptoms are of very short duration. One girl of 13 years with pain of one month's duration had already developed a hæmatotrachelos and a hæmometra. Another girl of 12 years with pain of less than twenty-four hours' duration in the right iliac fossa had her abdomen opened through a grid-iron incision, the pre-operative diagnosis being acute appendicitis. She proved to have a hæmatocolpos, hæmometra and a ruptured right hæmatosalpinx with free chocolate fluid in the peritoneal cavity. The occurrence of cases of this sort make it imperative that the drainage of a hæmatocolpos should be regarded as a surgical emergency. This drainage, by crucial incision or circular excision of the membrane, would seem a minor surgical procedure; nevertheless, mishaps may occur. The first patient in this series from 1896 died under the anæsthetic before the operation could be started. In 1907 excision of an unusually thick membrane was followed by a vesico-vaginal fistula which had to be secondarily repaired. In two instances, referred to later, post-operative infection involved the genital tract.

The occluding membrane varies considerably in thickness, in its precise situation and, possibly, in embryological origin. Many conformed to the clinical description in that they bulged at the vaginal orifice and were sufficiently thin and translucent to show the dark colour of the retained, altered menstrual fluid. In other cases the membrane was flat, up to half an inch in thickness and of the same colour and appearance as the surrounding vulval tissue. The hymen was frequently to be seen below the obstructing membrane but sometimes it could not be demonstrated as a separate entity, even when carefully looked for. In one case (1929) biopsies of both the hymen and the occluding membrane were taken for histological examination. The hymen was lined on both surfaces by thick, stratified epithelium. The membrane was lined on its outer surface by similar epithelium but on the inner surface the epithelium was much thinner and of a more transitional type. Between the epithelial layers many membranes contained muscle as well as collagen fibres and in some the inner lining was a high columnar epithelium.

In 7 cases the gynatresia was at a higher level than the vaginal orifice at varying levels in the vagina and cervix. 2 of these cases, in which the vagina was completely absent, are of particular interest. In one (1895) a girl of 19 was under observation for a year for recurrent monthly attacks of severe hypogastric and low back pain. At first the uterus, on rectal bimanual examination, appeared to be of normal size, but, later, it enlarged to the size and consistency of a 10 weeks' pregnancy. There was no vaginal orifice and, with a sound in the urethra and a finger in the rectum, no vagina could be felt. After dissecting about 1½ in. upwards in the cellular plane between the urethra and the bladder in front and the anal canal and rectum behind, two bulges in the depths of the wound appeared to represent distended cervices. Each was penetrated separately with sinus forceps by Hilton's method and each drained a considerable quantity of typical retained menstrual fluid. Convalescence

was mildly febrile for five weeks, during which time the cavity was first packed with iodoform gauze and then regularly dilated. A follow-up note stated that a vagina 2½ in. deep resulted, menstruation was normal and the uterus now felt quite small. This case would appear to have been one of double hæmometra in a septate bicollis uterus with a complete atresia of the vagina.

In the other case (1909) a girl of 17 years had had monthly attacks of pain in the lower abdomen and thighs for two and a half years. Two abdominal swellings were felt, one central and sub-umbilical, the size of a fœtal head at term, the other a fixed mass in the right iliac fossa. On rectal examination a thin fibrous cord could be felt where the vagina should have been. Laparotomy disclosed a small hæmometra (2 oz.) and large bilateral hæmatosalpinges (each 10 oz.). There were many adhesions. Subtotal hysterectomy was difficult; the right ureter crossed behind the cervix to the left side. The patient developed ileus and died on the eighth post-operative day.

Simple hæmatocolpos complicated by infection.—Three examples of this condition occurred in this series. In 1933 a patient of 25 years was sent to hospital with a six days' history of abdominal pain and difficulty in micturition. A tender swelling reached to the umbilicus. Excision of a low occluding vaginal membrane released a large quantity of foul-smelling blood-stained fluid which, on culture, grew an anaerobic Gram-positive coccus. In this case the infection of the hæmatocolpos preceded surgical intervention. In 1907 another patient attended hospital with a minute opening in an occluding low vaginal membrane and the vagina filled with foul pus. The membrane had been perforated and a hæmatocolpos drained with a trochar and cannula twelve months previously. A third case in 1911 was the girl who ruptured her hæmatocolpos by falling on her perineum. The rupture closed down and there was inadequate drainage of offensive, infected menstrual debris.

Unilateral Gynatresia with Unilateral Cryptomenorrhœa

There are 14 examples of this anomaly occurring with equal frequency on either side. In every case unimpeded menstruation occurred from the unaffected side. The atresia was at varying levels but in no instance was it very low down. In 5 cases a shorter vagina was intimately related to one side of the upper part of the fully formed vagina. In 4 cases this anomaly was on the right side and in 1 case on the left. Lower abdominal and pelvic pain led to the discovery of an abdomino-pelvic swelling in each case. In 3 the initial diagnosis was broad ligament cyst and in another it was tubercular salpingo-oophoritis. In 2 cases the retained menstrual fluid amounted to 2 pints; one of these patients died of post-operative peritonitis; the other has since had 6 children. In 1 patient, aged 15 years, there was no vagina on the affected side and the cervix was occluded at the level of the os externum. She developed a large right-sided hæmatotrachelos which was drained by vaginal trachelotomy. She has since had one successful pregnancy and is again 4 months pregnant at the present time. Both these pregnancies relate to the unaffected left genital tract.

In 6 cases there was a single vagina and cervix. The unilateral atresia consisted of occlusion of a rudimentary or accessory horn. The age range of these patients was wide and the majority were, perhaps, unexpectedly old. The ages at the time they received surgical treatment were 15, 17, 20, 28, 33 and 39 years. Initial diagnosis included ruptured ectopic pregnancy, Dietl's crises, intractable dysmenorrhœa and degenerating fibroid. All had abnormal pelvic physical signs, usually a tender, irregular uterine enlargement or a tubo-ovarian swelling. In 5 cases the abnormal horn was excised. In the patient aged 39 years a total hysterectomy was done.

Imperfect drainage of one side of a double genital tract with consequent infection.—In addition to the case that developed post-operative fatal peritonitis there were 2 cases of infection consequent upon imperfect drainage of one side of a double genital tract.

(1) A single girl of 21 years gave a history of a post-menstrual, very offensive, fæcal smelling, pale green discharge since her periods began at the age of 14 years. Repeated tests at a Venereal Disease Clinic were negative for such types of infection. Careful examination under anæsthesia defined a soft swelling adjacent to the right anterior part of the vaginal vault. Pressure in this region caused fæco-purulent pus to exude from the cervical canal. It was then discovered that an antero-posterior septum divided the cervix and that ¾ in. above the lower extremity of the right-sided canal a fistulous track led into an infected sac related to the right vaginal fornix. Through an incision in the right fornix around the side of the cervix the fistulous track was excised and the infected sac laid open and marsupialized into the right fornix. The discharge subsequently cleared up. Because of the resemblance

of many features of this case to those of the following one, the sac was probably produced by infection of an incompletely developed right-sided vagina.

(2) A girl of 14 years was referred to me because of an offensive intermenstrual discharge so overpowering that on several occasions she was sent home from school on account of it. She was placed on the waiting list for admission to hospital for examination under anæsthesia and other investigations, but pain in the right iliac fossa associated with pyrexia developed and admission to the general surgical side of another hospital was arranged. The abdomen was explored for what was now a subacute lower abdominal infection and a right-sided purulent salpingitis was found. The appendix was removed and the wound was drained. The pus grew *Bact. coli* on culture and appropriate chemotherapy was instituted. The infection subsided but two months later she was admitted to hospital with a tender mass in the right iliac fossa and complaining of some foul green vaginal discharge. Vaginal examination under anæsthesia now identified a very small sinus to the right of the portio vaginalis of the cervix. The mass in the right iliac fossa felt bimanually was larger than the uterus and pressure on it caused pus to exude from the sinus in the right vaginal fornix. A further, more extensive laparotomy now revealed a right-sided pyosalpinx and pyometra which were removed at the level of the cervix. A left-sided uterine body with the left fallopian tube and ovary appeared healthy. A ureteric catheter was introduced through the cervical canal of the stump remaining after the right uterus had been removed and a subsequent X-ray showed it to be coiled up in a cavity related to the upper half of the right side of the vagina. Dissection into this from below opened a right-sided pyocolpos which was widely drained. This girl had no kidney on the right side. She has had a satisfactory convalescence and is now menstruating normally from the left uterus.

Before leaving the subject of simple hæmatocolpos I shall refer to one case of hydrocolpos which I encountered at another hospital. A girl of 15 was referred to me on the same day that she developed acute retention of urine as the first symptom of what appeared to be a classical fairly large hæmatocolpos. There was nothing suggestive of infection or toxæmia. On incising the occluding membrane, which bulged at the vaginal orifice, 40 oz. of inoffensive creamy-white fluid escaped. This fluid was sterile and contained cellular debris, many squamous epithelial cells and a small number of leucocytes. She made a straightforward, afebrile convalescence and started to menstruate normally six months later. Maliphant (1948) published a report of a very similar case He pointed out that of the small number of cases reported, more have occurred in the neonatal than the pubertal age group. Such remarkable cases give rise to conjecture. Does this fluid represent a form of so-called "white menstruation" where the endometrium is not being subjected to, or does not respond to the influence of a hæmorrhagic factor, or does it represent an accumulation of non-menstrual secretion? Perhaps, in many cases of gynatresia, a quantity of such fluid has accumulated before true menstruation begins. If this is so, then there is a case for the excision of an occluding membrane without delay, should it be discovered before puberty.

There still remain the many anomalies of the genital tract where there is no cryptomenorrhœa. In these there is no gynatresia distal to menstruating endometrium. Their importance lies, perhaps, more in their effect on child-bearing and in their not infrequent association with anomalies of the urinary tract than in their symptomatology.

Incomplete transverse or longitudinal septa may modify the internal contour of the vaginal canal. Eleven transverse and six longitudinal septa of this incomplete type found in nulliparous patients are included in this series. In some instances they were identified as the cause of dyspareunia or post-coital bleeding. In the remainder they were discovered only when a vaginal examination was made antenatally or in the investigation of unrelated complaints. Some were dilated or divided and others were obliterated or disrupted in labour. In no instance did a septum materially modify the course of labour or occasion troublesome intrapartum or postpartum hæmorrhage or, in splitting, initiate serious laceration. There is no doubt that many septa of this type escape recognition before a first confinement and are largely obliterated by it. In one of these cases a patient in labour at term had a septum across the vaginal orifice, complete except for an opening near its centre which would just give passage to a medium-sized catheter.

Duplications of the genital tract represent failures or defects in the union between the bilateral components of the utero-vaginal canal. A median septum between the two sides is a transient feature of normal evolution but it may persist in varying degrees. Fusion between the uterine parts of the Müllerian ducts may have failed, again in varying degrees, from above downwards. Many terms have been coined in the literature to describe all these variants and the classification suggested by Monie and Sigurdson in 1950 has much to com-

mend it. "Didelphian" is defined by the Shorter Oxford English Dictionary as belonging to the subclass Didelphia of the class Mammalia, characterized by a double uterus and vagina and comprising the single order of Marsupials. Actually the formation of the genital tract varies in different species of marsupials; in some there is a medial vagina with two lateral canals.

In this series there are 20 instances of double vagina and uterus found in nulliparous patients. The anomaly was found once by the patient herself and in the remainder during pelvic examination. A few of the patients had complained of dyspareunia but the majority had no symptoms referable to the condition. 11 were under hospital supervision for a total of 20 pregnancies. 4 of these pregnancies ended in spontaneous miscarriage (20%), 6 were terminated by elective Cæsarean section near term (4 vertex and 2 breech presentations) and in the remaining 10 satisfactory vaginal delivery took place. In 6 the fœtus presented by the vertex and in 4 by the breech. All the infants were healthy and survived, the largest weighing 7½ lb.

In only one instance did the intervaginal septum persist after a first vaginal delivery and in this case the infant weighed only 4½ lb. In all the other cases the septum was either divided with scissors or disrupted itself in the second stage. In one case the upper half of the septum disrupted itself during breech delivery and a double footling presentation ensued, one leg coming down through each vaginal orifice. Progress was delayed until the lower part of the septum, on which the fœtus was seated astride, was divided with blunt-ended scissors.

The patient who discovered the anomaly herself was a generally trained nurse and midwife. When trying to insert a Tampax she found she had a double vagina. She was in the Far East at the time of her first pregnancy and was delivered by Cæsarean section partly because of the anomaly and partly because the presentation was a breech and several attempts to perform external version had failed. When home on furlough she sought advice as to whether it would be possible for her to have a natural labour. The situation was assessed and the vaginal septum was divided by cutting diathermy. Subsequently she had a successful vertex delivery and on the fifth day of the puerperium passed a decidual cast from the non-pregnant uterus.

One of my own cases, not included in this series, presented in her second pregnancy with a double vagina with the cervices fused medially. Her first delivery was by Cæsarean section because of a breech presentation. This pregnancy was in the left uterus. In her second pregnancy palpation and Lipiodol hysterogram confirmed it as being in the right uterus and delivery was by a further Cæsarean section.

The lesson to be learned from these cases is that vaginal delivery presented no serious difficulty or complication and, therefore, resort to Cæsarean section in such cases should not be made too readily.

Partial or complete duplication of the corpus uteri in association with a primarily single cervix and vagina constitutes a somewhat different clinical problem. The condition gives rise to no symptoms and the diagnosis is much more easily overlooked than when the vagina and cervix are double. Of the 11 cases in this series 6 were recognized in association with pregnancy. 2 of these were diagnosed antenatally and in both the presentation of the fœtus and labour were normal. In 2 the diagnosis was made after delivery, in 1 during manual removal of the placenta and in the other by abdominal palpation. The remaining 2 were diagnosed at laparotomy, in 1 for a tubal ectopic pregnancy and in the other for termination of a fifth pregnancy in a woman with severe morbus cordis.

I have had one case elsewhere, a young primigravida, with a persistent transverse lie which could not be corrected by external version. Delivery by Cæsarean section revealed a markedly bicornuate uterus with the fœtal head in one cornu and the breech and placenta in the other. A postnatal hysterogram confirmed the bicornuate shape of the uterine cavity.

In the absence of pregnancy the discovery of this anomaly has been very largely fortuitous as in (1) a grand multipara with procidentia, (2) a patient with carcinoma of the body of the uterus, and (3) a patient who sustained a separation of the symphysis pubis in labour. In the first and third of these cases a Lipiodol hysterogram was done and in the second it was recognized at laparotomy.

Many minor degrees of bicornuate uterus not included in this series have been revealed by Lipiodol hysterogram carried out in the investigation of infertility, spontaneous miscarriage and other gynæcological conditions. One, exceptionally pronounced, was found in a woman who had had four normal confinements without the condition having been suspected.

In reviewing this material I have been impressed by the infrequency of any association between recurrent abortion and a degree of septate or bicornuate uterus that might justify a plastic operation designed to create a uterus simplex. This was considered in one patient who had had three spontaneous miscarriages, but she was not anxious to submit to such an operation and was not pressed to do so.

Asymmetrical Duplications of the Genital Tract

My attention was directed particularly to these anomalies when I made a survey of the autopsy material accumulated by the Bernhard Baron Institute of Pathology at the London Hospital, where records are available since 1907.

Autopsies on female subjects (1907 to 1955)	11,362
Anomalies found:	
(1) Asymmetrical	
Unilateral uterus	13
Accessory horn	2
Rudimentary horn	2
(2) Symmetrical	
Bicornuate uterus	9
Arcuate septate uterus	1
Double uterus and vagina	2
(3) Agenesis	
Complete	1
Uterine	1
Incidence—1 in 366 autopsies.	31

These figures suggest that asymmetrical uterine anomalies are at least as common as the grosser symmetrical ones and, as they appear to be diagnosed less frequently, it is probable that they more often escape recognition.

Of 12 cases in the clinical series, 7 were associated with pregnancy. Five pregnancies were in the well-developed uterus. Two of these had breech presentations and were diagnosed at Cæsarean section, one had a laparotomy when an ovarian tumour was diagnosed obstructing the descent of the head into the pelvis, one had an abdominal hysterotomy and another had a laparotomy for an ovarian tumour which proved to be an ectopic pelvic kidney. The other two pregnancies were in the imperfectly developed side, one in a ruptured accessory horn and the other in a ruptured fallopian tube.

Of the 5 cases unassociated with pregnancy 4 were diagnosed at laparotomy carried out when lower abdominal or pelvic pain led to the discovery of an irregular uterine enlargement attributed in 3 cases to the presence of fibromyoma. In 1 case there was no lump but at laparotomy a cornu solidarius was found. The remaining case was diagnosed when a Lipiodol utero-salpingogram was carried out during the investigation of infertility. The diagnosis was confirmed when an intravenous pyelogram revealed only one secreting kidney on the same side as the unilateral uterus.

One of the Cæsarean sections was carried out in rather unusual circumstances. The patient, a doctor's wife, was found to have a breech presentation at 32 weeks but all attempts at version failed. She was a primigravida aged 22 years. X-ray pelvimetry showed a gynæcoid pelvis at the lower limit of normal as regards size. The fœtus did not appear to be unduly large so breech labour at term was decided upon. Labour was slow, the membranes ruptured early and the two feet came down to the vulva through a rather thick, incompletely dilated cervix. Lower segment Cæsarean section at this point revealed a left unilateral uterus which had been unsuspected. Both kidneys were normal to palpation.

This and other cases raise the question of the relationship between asymmetrical development of the genital tract and asymmetry in the development of the urinary tract. In the 17 cases found at autopsy:

Kidney absent on side of Müllerian agenesis	8
Both kidneys present and normal with complete unilateral Müllerian agenesis	2
Kidneys not specifically recorded	3
Both kidneys present and normal in 1 case of accessory horn and 1 case of rudimentary horn	2
Kidneys not specifically recorded	2

Among the clinical cases there were 16 other developmental anomalies of the genital tract:

Complete absence of vagina with rudimentary uterus. (Additional to one case associated with bilateral hæmometra already described)	9
Two-inch vagina, no uterus, no left kidney	1
Upper two-thirds vagina absent, no left kidney	1
Absent vagina with small left non-functional unicornuate uterus	1
Vaginal anus (congenital recto-vaginal fistula)	4

Selected Anomalies of the Urinary Tract

I have included 5 cases in this series where the anomaly is dominantly one affecting the urinary tract but I think it will be agreed that in each instance there is a particular obstetrical or gynæcological associated interest.

2 of these cases had *unilateral pelvic kidneys*. In 1 a pelvic lump was discovered during labour below the presenting part and obstructing delivery. Its nature was only recognized following a Cæsarean section. The other case presented in 1954 and the relevant features are as follows:

At the age of 16 years the patient had a spinal fusion performed for the treatment of a severe scoliosis. At the age of 21 she married. At the age of 25 years she attended the Out-patient Department because of infertility and right-sided lower abdominal pain. A pelvic tumour was felt somewhat to the right of the mid-line and near the pelvic brim. It was rather tethered and was thought to be an ovarian neoplasm with, perhaps, some degree of torsion of its pedicle. Laparotomy revealed that it was, in fact, a right-sided pelvic kidney with renal arteries arising from the common iliac and internal iliac arteries. The pelvis, as is usual in such kidneys, was lateral in position. The right cornu of the uterus was rudimentary but the left was well developed.

At the age of 26 years she had a quick, straightforward breech delivery from her left unilateral uterus. The kidney was palpable below the presenting part early in labour but the extending breech came down past it and labour was, therefore, allowed to continue. The infant weighed 6 lb.

Two further cases were found at autopsy, being unrecognized during life. In an adolescent girl the right kidney was situated in the false pelvis and the left in the upper true pelvis. The right cornu of the uterus was accessory and did not communicate with the developed left side. She died thirteen months after a road accident as a result of sepsis engendered by extravasation from the injured pelvis of the right kidney. The other subject had a left kidney situated in the false pelvis. Death at the age of 22 years was due to congenital morbus cordis.

A fifth case is warded at the present time. Her first pregnancy in 1946 was complicated by antepartum hæmorrhage, an oblique lie and the presence of a cystic swelling the size of an orange in front of the promontory of the sacrum. She was delivered by Cæsarean section when the presence of a placenta prævia was confirmed. The presacral swelling was retroperitoneal and extended to the right with the common iliac vessels crossing it laterally. It was thought to be a broad ligament cyst and was not removed. The patient is now pregnant again—about 22 weeks—and a cystic swelling lies in front of the upper sacrum. An intravenous pyelogram shows no sign of a renal shadow in the right loin. Catheterization of the right ureter produced a rapid flow of 35 c.c. of urine, and the diagnosis of a right-sided pelvic kidney is now a near certainty.

I have had another case at a different hospital: A single girl of 22 years, an identical twin, with a long-standing rheumatic carditis causing mitral stenosis and aortic incompetence, developed a right-sided pyelitis complicating a first pregnancy of 28 weeks' duration. At 34 weeks she further developed a severe progressive pre-eclamptic toxæmia and heart failure. The blood pressure was 160/90, there were 10 parts of albumin in her urine and she had massive œdema including the vulva. The presentation was a breech. After a short period of treatment she was delivered by Cæsarean section with sterilization. The uterus was right unilateral with a rudimentary left cornu. The right kidney was large and the left kidney apparently absent. She made a satisfactory convalescence and it became possible to investigate her genito-urinary anomaly more fully. The left kidney was situated in front of the 5th lumbar and 1st sacral vertebræ on the left side and was completely overlooked when the abdomen was opened. Her twin sister was investigated and found to have a normal genito-urinary tract.

Thom (1928) collected from the literature 117 cases of partial urinary incontinence due to the uncontrolled drainage of an ectopic ureter which opened on to the vestibule in 45, into the urethra in 37, into the vagina in 32 and into the uterus in 3. The 2% to 3% of individuals with duplication of the ureter on one or both sides do not belong to this category unless one or more of the ureters has an extra-vesical outlet. 3 patients in this series had partial urinary incontinence from this cause.

(1) Two accessory ureters opened into the vaginal vault in addition to the two ureters that opened in normal position into the bladder.

(2) A left ureter opened into the vault of the left side of a double vagina. A single ureter, the right, opened into the bladder. Neither an intravenous pyelogram nor an aortogram revealed any evidence of the presence of a left kidney. Eventually exploration of the left loin exposed a hypoplastic left kidney which was removed with complete cure of the partial incontinence. Methylene-blue injected into the ureter came through to the left vaginal vault.

(3) A woman aged 60 years had had 6 children and was twenty years past the menopause. She had always dribbled urine since "her mother dropped her as a small child." She went to her doctor having noticed blood in her urine and a blood-stained discharge, but a full renal investigation and a uterine curettage were both negative. Hæmaturia continued, now having been present for five months. During a pelvic examination a bead of blood-stained urine was seen to exude from a small opening in the mid-line 1 cm. behind the external urinary meatus. Mr. G. C. Tresidder, one of our urologists at the London Hospital, removed a right kidney with two pelves; about the upper one-third of the kidney was largely replaced by a Grawitz tumour.

In conclusion, and to maintain a due sense of proportion, I would refer back to uterus and vagina simplex—the heritage of the vast majority of womankind. Thereby I would emphasize once again that the anomalies which I have discussed affect but a very small proportion of women.

I would like to thank my colleagues, past and present, for the use I have made of their cases.

BOOK REVIEWS

Techniques and Procedures of Anæsthesia. By John Adriani, M.D. 2nd edit. (Pp. xiv+568; illustrated. 66s.) Oxford: Blackwell Scientific Publications. 1956.

The title of this book accurately describes its contents which are presented in a didactic tabular form with numbered sentences, opposite which are brief explanatory phrases giving some of the physiological, pharmacological or practical reasons for the opinions expressed. This method of presenting the information makes it difficult to stress the relative values of the various points which are considered, and unfortunately these are seldom even enumerated in the order of their importance.

The reviewer finds himself out of sympathy with this approach in a volume of this magnitude, and feels that the omission of any discussion of basic physiological principles has resulted not only in much needless repetition but has also tended to impair the value of many of the—admittedly condensed—opinions presented.

It may seem churlish thus to criticize a work which has been reprinted six times, but as it is now offered in a greatly enlarged second edition this failure to stress the important points out of a mass of tabulated data becomes more noticeable, and may even be considered misleading to the point of being dangerous.

The section on succinyl-choline, for example, includes without any amplification other than that it is a disadvantage of the drug, the statement "In some individuals an apnœa may result (central depression)". It is not made clear that respiratory paralysis from peripheral neuro-muscular block is to be expected in every case, except perhaps when only extremely small doses are administered. On the other hand the section on controlled respiration makes no mention of the relaxant drugs which so facilitate this now commonplace procedure and obviate the necessity of giving large doses of drugs which depress the central nervous system. To the English anæsthetist the cursory mention given to the muscle relaxants and to controlled respiration is indeed surprising in an anæsthetic treatise published in 1956.

He will also feel, perhaps, that in the section on spinal analgesia the author lags behind contemporary thought in not stressing the importance of autoclaving all drugs and equipment used for this purpose. Again, in the section on rectal anæsthesia there are nine pages devoted to the obsolescent Avertin while a further page is given to trichlorethanol—a drug long abandoned in this country as too dangerous.

There are many other opinions expressed in these pages which invite comment, but the author in his introduction has disarmed the critic by pointing out the impossibility of assembling a book of techniques which would please every anæsthetist; as he rightly says the subject is not one to be learnt from a book.

Nevertheless, this volume contains much useful information; it will give the junior anæsthetist an idea of the wide scope of his specialty and of the many procedures he will have to study, and may also provide his teacher with some conveniently assembled data on which to base his lectures.

Atlas of Exfoliative Cytology. Supplement 1. By George Papanicolaou, M.D., Ph.D. (Illustrated; 32s.) London: Harvard University Press. Cumberlege. 1956.

The present supplement—the first to be issued—to Dr. Papanicolaou's Atlas of Exfoliative Cytology contains sixteen new coloured plates together with the appropriate letterpress. Most of the plates present three photomicrographs of each tumour—two of conventional histological sections at low and high power and one of cells from the same neoplasm as seen in exfoliative smears. Such comparisons are of great value to pathologists seeking to learn more about these newer diagnostic methods and to correlate the appearances in smears with those in paraffin sections with which they are more familiar.

In this supplement, four new plates each are devoted to the female genital and the respiratory systems, two each to the male genital and the digestive systems and the remainder to the breast and to various exudates. The technical production of these coloured plates is of a very high quality, and when used by pathologists who have mastered the author's staining techniques—as described in the main volume—the illustrations included in this supplement should prove of further help in accurate exfoliative cytological diagnosis.

Blood Transfusion in Clinical Medicine. By P. L. Mollison, M.D., M.R.C.P. 2nd edit. (Pp. xxv+587; illustrated. 45s.) Oxford: Blackwell Scientific Publications. 1956.

Dr. Mollison's monograph, now in its second edition, is, in the reviewer's opinion, without question the most complete and authoritative work on blood transfusion now available in English. It is particularly valuable because it is written by a man whose extensive and

perhaps unique practical and research experience in this field dates from the beginning of World War II and the discovery of the Rh blood groups, and it is a reminder of the astonishing progress that has been made in the understanding of the human blood groups and blood transfusion since that time.

As is right in a book which is primarily based on, and illustrated by, the author's own experience, Dr. Mollison does not confine himself strictly to the laboratory and clinical sides of blood transfusion; he enriches the text by including most valuable chapters and sections on subjects on the fringe of his main theme, such as blood volume, normal blood findings in infants, hæmolytic disease of the newborn, the use of ^{51}Cr-tagged cells in red-cell survival studies in disease and the use of ^{51}Cr in tracing the survival *in vivo* of red cells which have been exposed to isoantibodies.

The whole book is, in fact, packed full of up-to-date information on almost every possible facet of blood transfusion in theory and practice, and it includes three chapters of remarkable clarity, revised in collaboration with Miss Marie Cutbush, B.Sc., on the human blood groups. The bibliography at the end of the book now contains about 1,200 entries, and the inclusion of the titles to the references makes them particularly valuable.

This new edition, which is most meticulously produced, is 131 pages longer than the first edition published in 1951, but it is only 7s. 6d. more expensive. Every serious worker in the field of blood transfusion, whether physician, hæmatologist or clinical pathologist should possess a copy.

Principles of Chest X-Ray Diagnosis. By George Simon, M.D., F.F.R. (Pp. x+183; illustrated. 50s.) London: Butterworth & Co. (Publishers) Ltd. 1956.

The time is opportune and the need great for a re-statement of the principles underlying the interpretation of radiographs of the chest and no one is better qualified by his experience as a teacher to undertake this task than Dr. Simon whose present work fully justifies its title. It is essentially a teaching book in which the author happily excludes excessive clinical detail in order to concentrate on radiology. Radiographic technique in the form of "some hints" is brief and properly relegated to a terminal appendix, and anatomical considerations are confined to radiological landmarks and their variations. The interesting chapter classification is based on the characteristics of the particular radiological pattern, the shadows and translucencies being grouped according to their size, shape, distribution and outline and in each case the probable underlying pathological condition is indicated. This is a reversal of the normal textbook procedure of considering the radiological appearances under the heading of each of the various diseases in turn. Simon's method is, therefore, that of deductive interpretation, the daily system of the practical radiologist. He discusses most informatively the causes of common anatomical variations and explains some of the puzzling yet often normal features of lateral and oblique projections—for example, the high diaphragmatic cupola which simulates a pleural effusion. The chapter on mediastinal and diaphragm shadows is particularly helpful though the causes of diaphragmatic alterations could have been dealt with more fully. Simon demonstrates very clearly how difficulties in interpretation may arise from shadows cast by ribs or superficial tissues and how apparent "abnormalities" may be the result of even minor deviations from standard positions during radiography.

The use of the various radiological "indicators" is explained, particularly the diaphragm, the mediastinum, the lung fissures and the pulmonary vessels and there are strikingly instructive illustrations of segmental and lobar atelectases and consolidations. The author does not restrict himself to the classical appearances in each case but considers the modifications determined by pre-existing conditions, as instanced by the altered picture of middle lobe collapse when the main fissure is tethered.

Perhaps the sections which are likely to have most appeal because of their great practical value are those dealing with the classification of homogeneous shadows or discussing the nature of linear, ring and large circular opacities and there is an impressive list, which must be almost exhaustive, of the possible causes of disseminated, small, circular or reticular shadows. Bronchography and tomography are somewhat briefly dealt with although their uses and indications are clearly described. Readers would have been grateful for discussion of those shadows which constantly give rise to difficulty in tomographic interpretation. The large format has made it possible to include illustrations of a size adequate to demonstrate the points described in the text and the chapter and section headings in large clear type facilitate reference.

There are no major defects in this excellent book.

A minor fault is the author's use of terms that are either not in general use or have been discredited but in fairness to the reader he does define his own terms in the introductory chapter. The author's clear descriptive writing and his skilful use of magnificent illustrations and textual tables make this work, in the reviewer's opinion, easily the best teaching manual on chest radiology.

Anatomical Techniques. By D. H. Tompsett, B.Sc., Ph.D. (Pp. xvi+240; illustrated. 35s.) Edinburgh and London: E. & S. Livingstone Ltd. 1956.

This book is written primarily as a guide to part-time workers and prosectors who require some ready available information on the preparation of museum specimens of human anatomy. On the technique of dissection, much of what Dr. Tompsett has written has been known since dissections were first undertaken many centuries ago. Nevertheless it is useful to have this information available in print. On the mounting of anatomical material in Perspex containers there is much useful information and the detailed instruction given on the preparation of casts in synthetic resins makes a real contribution to anatomical techniques. Although some of these techniques are very highly specialized, many of the others are becoming a necessity for the proper understanding of the anatomy of such organs as the lung. Dr. Tompsett was one of the first persons to appreciate the possibilities of the synthetic resins in place of woods, metal and plaster of Paris which were formerly used.

The chapter dealing with the principles of anatomical illustration leaves much to be desired, but presumably this is not the author's field. In Fig. 26, which is taken as a prototype, the pointers are arranged in such a way that many of them run parallel to each other so that they look like railway lines. Interrupted lines are always preferable to continuous ones, as they do not cut up the illustration so much. This figure would have been much better reproduced as a simple "cut out" with the lettering arranged independent of the half-tone screen. In spite of this criticism the book can be recommended without reservation. It is well produced and is a credit to the publishers, E. & S. Livingstone Ltd.

Management in Obstetrics. By Andrew M. Claye, M.D., F.R.C.S., F.R.C.O.G. 2nd edit. (Pp. x+218; illustrated. 18s.) London, New York, Toronto: Oxford University Press. 1956.

This is a second edition of a book, first published in 1948, which has gained well-deserved popularity. It is not a textbook, but rather a series of essays covering the range of practical obstetrics. This second edition has grown in size, and the number of illustrations has increased. The text has been thoroughly revised and the references brought up to date.

This book is chiefly intended for the general practitioner obstetrician to whom it can be warmly commended on account of the lucidity of its style and the emphasis always on the practical. It is useful, either as reading matter or as a work of reference. The quotations which head many of the chapters are often delightfully apt and reveal the author not only as an obstetrician but one with a profound knowledge of English literature.

The new edition of this useful book will prove a contribution to the further raising of standards of midwifery and it will be of value, not only to the general practitioner for whom it is mainly intended, but also to all who practise the art of midwifery.

Neoplasms of the Domesticated Mammals. A Review. Review Series No. 4 of the Commonwealth Bureau of Animal Health. By E. Cotchin, M.R.C.V.S. (Pp. xv + 100. 20s.) Farnham Royal, Bucks.: Commonwealth Agricultural Bureaux. 1956.

This monograph, as the author states in the introduction, is a survey of the incidence of tumours in domesticated mammals, and is not a histopathological treatise.

No one is better qualified, in view of his extensive study of animal neoplasms, than Mr. Cotchin to undertake this detailed comparative survey. The omission, however, of any histological description of the neoplasms does not in any way detract from the usefulness of this handbook. It is something more than a critical review since it compares the tumour incidence in different animal species with that of man, and therefore contains information of interest to both the clinician and laboratory worker who are interested in the cancer problem.

The author begins with an admirable introduction extending over eight pages, which deals not only with the statistical study of tumour incidence, but also the mechanism of the spread of cancer in different animals. Apparently in some species metastases may occur by different routes than in man. In the subsequent chapters the author brings to light some interesting facts: the cat, for instance, would seem to be the most useful species in which to study carcinoma of the œsophagus, since it is the only domesticated mammal apart from man in which spontaneous cancer of that organ frequently develops. Methods are also discussed by which neoplasia can be experimentally produced in the organs of some species; information which is of direct interest to those engaged in tumour induction. Furthermore, we learn that melanotic tumours in the cat are very rare, whilst they occur often in both the dog and the grey horse. Also, we find that neoplasms of the mammary gland are particularly frequent in the bitch but are chiefly of the benign type, whilst although they occur less frequently in the cat they are invariably present in the malignant form. Carcinoma of the stomach and gall-bladder, both of which are common in man, are

apparently rarely met with in domesticated mammals and, when they do occur, they are diffuse or hyperplastic rather than neoplastic. It is curious to find that carcinoma of the prostate, which is frequently seen in man, is very rare even amongst the higher mammals; but, on the other hand, testicular tumours are particularly frequent, especially in both the dog and horse.

These comparative studies are not only of interest, but are of importance, when dealing with the ætiology of cancer, since any explanation for their rarity in some animals might help to explain the cause of a particular neoplasm common in man.

As a work of reference this monograph is well constructed with clear headings to the numerous sub-sections of each chapter. There is also an excellent bibliography of nearly a thousand references, all of which have been read by the author.

The Collected Papers of Paul Ehrlich. In four volumes. Volume 1—Histology, Biochemistry and Pathology. Edited by F. Himmelweit, M.D., Ph.D., F.R.C.P.Ed. (Pp. viii + 653; illustrated. Volume 1—£12.) London and New York: Pergamon Press. 1956.

This work may, without exaggeration, be described as one of the most ambitious and important contributions made to medical literature and medical history this century, and doctors, scientists, historians, and librarians owe an enormous debt of gratitude to the editor, Dr. Himmelweit, to the late Martha Marquardt, to Sir Henry Dale, to the Pergamon Press, and to the Wellcome Trust for the part they have played in translating what might well have remained a pious dream into the realm of reality. The first volume contains a scholarly and enlightening introduction by Sir Henry Dale and 55 of Ehrlich's papers which are arranged in the following sections: Practice and theory of staining in histology; Cytology of the blood in health and disease; Staining of bacteria and its application to diagnosis; "The requirement of the organism for oxygen" and allied biochemical studies; Pharmacology, therapeutics, and toxicology; The diazobenzenesulphonic acid and dimethylaminobenzaldehyde reactions. The earliest paper is dated 1877 and the last 1904. The great majority of the articles are in German. Two previously unpublished ones are also translated into English: Ehrlich's inaugural dissertation (Leipzig, 1878), entitled "Contributions to the theory and practice of histological staining", and his *Habilitationsschrift* (thesis for recognition as university teacher), "The requirement of the organism for oxygen: an analytical study with the aid of dyes" (1885). There are five coloured plates and a frontispiece showing Ehrlich aged about 40.

Having enjoyed the literary feast provided by this unique and fascinating volume, it may be greedy and ungrateful to ask for more, but to the reviewer it seems a great pity that a few lines of comment did not accompany each article, explaining its historical significance and its value to-day.

The price per set is £28. Volumes 1, 2, and 3 can be bought separately for £12 each; the final volume which will contain a complete bibliography, will not be sold separately, but will be available with any other volume at £5.

Pathological Histology. By Robertson F. Ogilvie, M.D., D.Sc., F.R.C.P.Ed., F.R.S.E. Foreword by A. Murray Drennan, M.D., F.R.C.P.Ed., F.R.S.E. 5th edition. (Pp. xi + 482; illustrated. 52s. 6d.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

The fact that this book has been re-issued seven times since its first appearance in 1940 attests the appreciation that has been accorded to it by large numbers of the medical students for whose training in morbid histology it was originally prepared. The present edition has been further enlarged, and the author hopes that this expansion will render the volume of greater value to more advanced readers.

The general standard of the coloured illustrations, of which there are more than three hundred, is satisfactory, though in spite of the weeding that has taken place in successive editions, a number could still be bettered. Most of them are made from the hæmatoxylin and eosin stained sections with which students are generally familiar, though other methods are used when needed for the display of particular structures. The book can therefore be employed usefully as a bench manual in morbid histology classes, though, as Professor Drennan remarks in his foreword, "No book on morbid histology can ever replace study of the actual specimen, but a book may so vividly represent and interpret the original that its study is greatly facilitated and revision of knowledge simplified."

Whether or not with the increasing competition for time in the curriculum, the student's limited period of study in a pathology department is most profitably spent in such a detailed examination of this branch of morbid histology is a matter which each teacher must decide for himself. In the reviewer's opinion there are other aspects of pathology, functional and biochemical, that nowadays are equally, if not more, rewarding.

[*November* 13, 1956]

DISCUSSION ON THE TREATMENT OF MORBID ANXIETY [*Abridged*]

Dr. E. A. Bennet: *Psychotherapy*

The treatment of the morbidly anxious patient, by psychotherapy, should be confined to those who are emotionally and intellectually capable of co-operation, and a patient should not be accepted for treatment unless the diagnosis has been made on affirmative grounds, that is from the presence of the known characteristics of the state of disturbing and irresolute suspense which we describe as morbid anxiety. In making a diagnosis we aim at probabilities, approximations, rather than certainties; and the diagnosis may well be altered as we observe our patient. But this does not permit us to commence treatment on the basis of an ambiguous diagnosis or a negative diagnosis which infers psychological illness from the absence of organic disease. Whatever its form and whether combined with physical methods of treatment or not, psychotherapy is a co-operative procedure in which one person seeks to influence the health of another. It is essentially the interaction of two personalities. Jung (1933) puts the matter concisely: "By no device can the treatment be anything but the product of the mutual influence in which the whole being"—that is the personality, containing both conscious and unconscious elements—"of the doctor as well as that of the patient plays its part."

The relation of doctor and patient on a consciously harmonious level, as in our association with acquaintances, is described as "rapport". But when the unconscious of either doctor or patient is clearly involved, "transference" is a better term. Transference occurs whenever psychotherapy goes beyond the superficial level, and as it is a phenomenon of projection we cannot know to what extent the therapist and the patient will be involved. The interaction of the personality of the doctor and that of the patient means more than medical empathy, that is the doctor's ability to value the feelings of his patient, for the patient's valuation of the doctor's feelings also plays a part. The therapist will try to understand his patient and he must expect the patient to return the compliment. We encourage our patients to be natural, to drop pretences, knowing that the inner will affect the outer anyhow, and we should do the same. There is a danger that the analyst who has difficulty in making personal relations within or without the analytical sessions, may unknowingly protect himself behind the patient's manifestations of transference, denying his own part in the proceedings, although his projections, like those of his patient, are active ingredients. Successful psychotherapy is a joint effort, the product of the whole influence of each personality. While it is unreal to believe that every contact between therapist and patient is or should be within the transference situation (for rapport also provides possibilities of treatment), it is equally unreal for the therapist to regard transference as an abstraction with which he is not concerned. Whether he concerns himself with it or not, it will still be there, playing its part. My own opinion is that transference is of central importance, but that it is a mistake to make it the main focus of attention; nor need it always be analysed. It is a medium of contact, for good or ill, in which the

unconscious of the patient and that of the doctor can evolve and develop. Often the unspoken is more valuable than the spoken word.

The division of the neuroses into hysteria, anxiety and obsessional states, though deceptively simple, has one thing in its favour: it helps us to see that the energy, the drive behind psychoneurotic and similar symptoms, is differently directed, achieves its purpose in different ways. The attitudes, that is the activities represented in symptoms of neurosis, call for something more than an ætiology framed solely on a simple developmental or cause and effect plan. In addition we should observe the attitude of the patient towards the movement of life, the passage of time. Bearing this in mind, I should place hysteria at one end of a scale and obsessional states at the other, with anxiety-states occupying an intermediate position. The patient with hysteria meets the present as if it were the past. In a fugue, for example, the dissociated individual wanders, not aimlessly but purposively, seeking to return to a place where once upon a time life was almost problemless; and should the morbid anxiety undergo conversion we have an attitude of dependence, even of childishness. It is this application of past notions to present problems which makes hysteria so resistant to treatment. On the other hand, the obsessional patient, who is always morbidly anxious, meets the present as though it were the future. The patient with the typical symptoms of an anxiety state falls between these two, for he is rooted in the present and cannot see either the past or the future in its true perspective. The relevance of these observations to the treatment of morbid anxiety will be illustrated if we consider some features in the group of patients with obsessional symptoms.

Three characteristics, usually found in combination, call for special attention in the treatment of obsessional patients: these are (1) a conscious sense of guilt; (2) secrecy regarding the symptoms—the obsessional neurosis is the secret neurosis; and (3) what for lack of a better term I call the time element.

(1) The patient with a compulsion to pursue repetitive actions or thoughts feels guilty and oppressed because of the content of his symptoms, which nevertheless fascinate him. Consciously he loathes his acts or thoughts, yet their interest-value compels him to cling to them, and at the same time the conscious sense of guilt permits him to feel exonerated from the burden of responsibility for them. In consequence he has an insoluble problem: his conscious sense of guilt imparts a feeling of righteousness because of the condemnation of his compulsions, thus enabling him at the same time to own and yet to disown the satisfaction which his interest provides. The creation of an insoluble problem, such as this, is indeed one of the characteristics of the obsessional neurosis.

(2) The existence of the neurosis is a closely guarded secret and insulates him from others. But the secretiveness has its value, for like the guilt it preserves the symptoms, and close friends or relatives may be unaware that the patient has any symptoms, let alone their nature.

(3) Morbid anxiety in the obsessional patient is anxiety about the future on which his eyes are fixed almost to the exclusion of the present. His symptoms are an attempt to influence the future by magical thinking. Filled with morbid expectation he is deeply concerned with the passage of time. A patient of mine had a phobia concerning clocks and particularly clocks which struck the hour: "Time runs, the clock will strike." The striking of the clock sounded a note of inevitability—the time had come for something to happen. "Time, the subtle thief of youth" provides the insoluble problem of the obsessional, for all obsessional rituals aim at making time stand still. Behind the neurosis lies a morbid fear of the future and with it the thought of death. Thus the obsessional with a show of efficiency over current affairs (which deceives himself and others) is surprisingly ineffective. Intellectually he is often gifted but, being all for delay, he falls short of the goal which his attainments warrant. In him we see the hidden wish that "time may cease and midnight never come". More than any other, the obsessional patient is hurt and hindered by morbid anxiety and I suggest that the consideration of these three characteristics —the sense of guilt, secrecy and the time element—give an insight into his mind which is invaluable in treatment. It is difficult to understand how anyone can treat an obsessional neurosis, or any neurosis, purely by a reductive technique.

When it is possible—and often it is—to help a patient (obsessional or otherwise) to see the state of affairs behind the morbid anxiety with which his symptoms are clouded, then he has taken the first step towards being a more effective and much less anxious individual. He acquires a respect for his mind, conscious and unconscious, in its personal and impersonal aspects. To achieve this enlargement of consciousness we give the chief place in the treatment of morbid anxiety to dream analysis and to the use of drawings and paintings to amplify the dreams and particularly their symbolic content, as well as the product of active imagination. The patient is thus in the treatment, sharing the work with the

therapist. Consequently the interviews can be spaced out, often being weeks apart, till the patient, no longer bound by morbid anxiety, takes over responsibility for himself.

REFERENCE

JUNG, C. G. (1933) The Practice of Psychotherapy. *Collected Works, Vol. 16*, London, p. 71.

Dr. H. J. Shorvon: The appreciation of the physiological basis of anxiety, as well as the psychological, and the viewpoint that much morbid anxiety is the result of conditioning, has led to the approach whose aim is the disrupting of conditioned patterns of anxiety by chemical or other means.

Before and during the First World War there were only psychotherapy, hypnosis, bromides, paraldehyde and opiates. Barbiturates were not used before 1930. Sodium amytal in 1930 and Seconal in 1935 were the first of the barbiturates to come on to the market. Drug abreaction techniques were developed during the last war, first with intravenous barbiturates in 1940, and then under open ether by Palmer in North Africa and later by Sargant and myself at the time of the Normandy campaign. Modified insulin for sedative and nutritional purposes was first used on a large scale by Sargant at the time of Dunkirk. In 1944 Rogerson introduced the inhalation of nitrous oxide for abreactive and psychotherapeutic purposes, and in 1948 Meduna began his passive treatment of anxiety states by the repeated inhalations of a 30% carbon dioxide mixture. Sargant introduced intravenous Methedrine as an abreactive agent in 1948, and López-Ibor in Spain in 1950 found intravenous acetylcholine of value in certain types of tension. In 1950 Hirschfeld and Alexander in America tried subconvulsive electrical stimulation for the treatment of tension states, and this therapy was established in this country soon after by Spencer Paterson. Also since the war, the antihistaminic drugs such as Phenergan have developed and played an important part in treatment. In the past few years many "tranquillizers" have appeared on the market. The word is meant to indicate a drug which will ease anxiety and psychomotor agitation without affecting consciousness to any extent.

The personality of the patient, the intensity of his symptoms and whether his morbid anxiety is a manifestation of an anxiety state or secondary to some other disorder, such as melancholia, an obsessional state, &c., must be assessed before the value of the particular tranquillizer can be judged.

Some random observations on the use of these drugs may not come amiss. Bromides may be very useful in easing severe tension, but are apt to aggravate depression, and should be avoided in the aged, especially where renal function is impaired. I have recently seen two cases of addiction and repeated overdosage with Persomnia tablets, which unfortunately can be bought over the counter. They showed tremors, acneiform eruptions, ataxia, and spells of confusion with paranoid ideas and hallucinations.

The short-acting barbiturates have no superior in easing morbid anxiety. Addiction is rare although habit formation is commoner, and patients usually cut down the prescribed dose on their own initiative. Unfortunately, excessive dosage over a prolonged period may engender or exacerbate anxiety instead of relieving it. Seconal, ¾ grain, and sodium amytal, 1 grain, are the most effective drugs for immediate relief of acute panic or fear. The use of barbiturates in continuous narcosis is well known, but care must be taken in their withdrawal, particularly in obsessional personalities who may even show schizophrenic-like symptoms for a few days. I rarely use long-acting barbiturates such as phenobarbitone in the treatment of anxiety, because of depressant effects.

Antihistaminic drugs such as Phenergan are useful, particularly with patients in bed who tolerate 150–300 mg. daily, and I have also found the drugs of value in the relief of tension in sufferers from generalized pruritus and other psychosomatic disorders. They combine well with chlorpromazine in controlling agitation and restlessness.

Chlorpromazine or Largactil, the first of the tranquillizers, has been tried extensively since 1952. Most ambulant patients dislike it as they often feel tired and derive little easing of tension. Linford Rees and Lambert did, however, find that 50% of 150 patients showed considerable clinical improvement although two-thirds relapsed within a few weeks despite continued medication. Jaundice is an important complication, usually occurring within the first ten days of taking small doses. The drug, however, is very useful in in-patient treatment of acute anxiety reactions and for acute psychotic illnesses such as manic or schizophrenic excitement if given in bigger doses of 50–100 mg. three times a day,

or more.. It combines well with barbiturates in continuous narcosis, and is useful in combating a post-E.C.T. flare-up of tension or damping down the anxiety of the agitated melancholic. A feature is its tendency to increase appetite, and gratifying results are often obtained when combined with modified insulin.

Mephazine or Pacatal is chemically related to chlorpromazine and is said to have fewer side effects apart from dryness of mouth and blurring of vision. I have found it useful in easing tension of patients suffering from involutional depression who are not responding to E.C.T.

Reserpine or Serpasil, a rauwolfia alkaloid, can be regarded as still on trial. It is mildly hypotensive, and useful in patients suffering from hypertension with anxiety. In large doses of 8–10 mg. daily it can control the motor over-activity and aggressiveness of manic and schizophrenic excitements. Toxic side effects, Parkinsonism and œdema are not uncommon complications. Depression is a serious risk in patients on large doses. I use it very little in out-patients because of the unpleasant side-effects of tiredness, congestion of nose, diarrhœa and depression, but, like chlorpromazine, it tends to increase appetite and has been useful in conjunction with modified insulin in treating anorexia nervosa.

More recent tranquillizers, part of the feverish search for a panacea for anxiety, include benactyzine compounds (Suavitil, Nutinal, and Covatin), the meprobamates (Equanil, Miltown, and Mepavlon) and hydroxyzine compounds such as Atarax. Little is known of their pharmacological or possible harmful effects. Suavitil has received enthusiastic notice in Scandinavian papers by Jacobsen, Munkvad, &c., and in the *British Medical Journal* by Davies. It is said to produce a barrier between the patient and his problems. Lieberman and Vaughan in a recent paper consider this drug the best of the newer tranquillizers in the treatment of diffuse non-specific anxiety and tension. I have not found this to be the case with the majority of my out-patients on this drug, and indeed most anxiety patients asked to be taken off it. I used a total of 3 mg. daily. At St. Thomas's Hospital, da Fonseca and West carried out a trial of benactyzine and found it useful in anxiety reactions due to environmental stress and panic attacks in obsessive personalities. They, too, were disappointed with the overall results.

Perhaps the most widely used new tranquillizer is meprobamate, despite its cost. According to West and da Fonseca, Miltown has become the fourth most commonly prescribed drug in America and there is no doubt that Equanil, the same drug in England, is greatly in demand. The chemical formula is closely related to mephenesin, and in doses of 400 mg. (one tablet) three times a day it has been hailed in the U.S.A. as *the* drug for reducing morbid tension and anxiety because of its muscle relaxant and sedative effects. It is also said to be a fifth as toxic as barbiturates and not liable to create addiction. West and da Fonseca in the Psychiatric Department of St. Thomas's carried out three separate controlled trials. They found that 58% of patients classified as anxious and tense were helped. The results were not so good as those claimed by American workers. The relief was in the subjective sphere rather than in overt somatic manifestations of anxiety. Meprobamate was also compared with sodium amytal in a further series but no marked differences were found in effectiveness between these two drugs. However, clinically, meprobamate often seems more useful than a barbiturate when irritability is a marked feature. No serious side effects were observed. It therefore appears that Equanil has the beneficial effects of barbiturates, but with less risk of toxic complications and addiction. Although I have not carried out statistical trials, I have used meprobamate on a large scale in a variety of psychiatric syndromes and found it a useful drug in the out-patient treatment of anxiety states, particularly phobic states, fears of insomnia, and other mono-symptomatic fears. I have often seen the drug slow down feelings of impatience and frustration, but it also increased dullness in the morning and depression. It is best avoided where a depressive element is present in the illness. It also appears to reinforce the effect of barbiturates, and is therefore useful when added to such hypnotics at night, in order to reduce the total barbiturate consumption and to facilitate sleep.

A combination of stimulant and sedative drugs, for instance, Drinamyl, is particularly helpful in phobic anxiety states in an obsessional setting. The obsessional patient feels at his best when cortically stimulated, yet soothed at the same time. The result is activity in a relaxed and optimistic mood.

López-Ibor in 1950 introduced repeated intravenous acetylcholine injections in the treatment of tension states. Sargant, Phillips and Hutchinson found it useful with patients of good personality suffering from phobic tension states, particularly in driving personalities who carried on their work despite periods of debility. Hawkings

and Tibbetts have questioned these results, but their clinical material does not appear to correspond.

Abreactive techniques were fully discussed in papers in the R.S.M. in 1950 and 1953. Intravenous barbiturates were first used at the time of Dunkirk, and the excitatory abreaction of traumatic experiences in people of reasonably good previous personalities facilitated an emotional release, and often prevented the implantation of recently acquired neurotic patterns of behaviour. Soldiers in a state of acute fear and showing tics and violent movements of all kinds, in addition to hysterical inhibitory phenomena such as amnesia, aphonia and paralysis, felt "a load off their minds" after effective abreaction. It was usually necessary to follow this up with adequate sedation for some days, if the patient was to emerge into, and remain in, a state of mental equilibrium. This approach is, of course, equally useful in the treatment of anxiety states following traumatic episodes in civilian life. It was found later in the war that in untreated or inadequately treated cases, the neurotic reactions had become firmly established as a result of anxious rumination over unrelieved traumatic incidents.

Intravenous barbiturates failed to reactivate the affect attached to those experiences, and a dull recital of facts ensued, without benefit to the patient. During the Normandy campaign ether inhalation on an open ether mask was found to produce stronger excitatory abreactions in the acute psychiatric battle casualties than the barbiturates, with a correspondingly greater relief of anxiety and tension. Similar difficulties with the intravenous barbiturates were again experienced in more chronic cases, but the occasional ether abreaction still may be a useful procedure from time to time in the treatment of chronic anxiety states where traumatic incidents have played an obvious part in the precipitation of symptoms. The most difficult patients to treat, the anxious obsessionals, may be helped by intravenous Methedrine in small doses of about 15 to 20 mg., used either as a psycho-therapeutic aid or for encouraging abreaction. The drug relaxes the patient and reduces inhibition by cortical stimulation, so that everything is discussed with a feeling of confidence in extra-clear consciousness. Barriers are rapidly broken down, much repressed material is brought to the surface, and a good deal of tension is released over a period of time.

I also find that psychotherapy with the aid of intravenous Methedrine, and the occasional use of ether abreaction where there is some resistance to be overcome, or traumatic incidents to be discussed, is one of the best ways of treating phobic anxiety states with panic attacks, and psychosomatic disorders, such as skin disturbances resulting from emotional factors.

The pharmacological and clinical actions of the older drugs, bromides and barbiturates, have now been fairly well worked out, but few controlled studies have yet been carried out with the host of new tranquillizers. Little is known therefore about their mode of action and the indications for their use. Some may prove useful, and I suspect the majority will be discarded in time as the evidence about their value is slight.

President—PHILIP J. JORY, D.S.O., F.R.C.S.

[*November* 2, 1956]

Mr. PHILIP J. JORY delivered his Presidential Address entitled **Random Reminiscences.**

[*December* 7, 1956]

DISCUSSION ON NOISE AND ITS EFFECTS

Dr. J. D. Hood (Otological Research Unit, Medical Research Council, National Hospital, Queen Square, London):

Measurement of Noise

Noise may cause physical damage to the organ of hearing. It may interfere with communication. When unwelcome, it may give rise to mental irritation, and from this is derived what is perhaps its best-known definition, namely, that noise is any unwanted sound.

All of these ill-effects are related to certain of its physical attributes, in particular intensity and frequency. These can be measured, and it is the aim of this communication to outline firstly the technique of such measurements and, secondly, to relate their results to the frequency and intensity characteristics of the hearing mechanism itself.

Noise can be transient, periodic or aperiodic. In general, transient sounds consist of short duration changes of pressure; periodic sounds are those which can be shown to be repetitive over a certain period known as the fundamental period, and aperiodic sounds are those which show no particular period of recurrence. Sound intensity is measured by means of a calibrated instrument consisting essentially of a microphone, an amplifier and an indicating meter.

Table I affords some illustration of the intensity range with which we have to deal. If the normal threshold of hearing at 1,000 c/s be taken as the basis of our measurements, it will be seen that the noise level of a quiet office has a relative figure of 1,000, a busy street of 1,000,000, and thunder almost a billion. To accommodate this enormous range of intensities it is convenient to convert the relative intensities into decibels.

The relationships are apparent from Table I. A tenfold increase in sound energy corresponds to 10 db., a 100-fold to 20 db., 1,000-fold to 30 db. and so on.

TABLE I

	Relative intensity	Intensity in db. re 10^{-16} watts per sq. cm.
Threshold of hearing at 1,000 c/s 10^{-16} watts per sq. cm.	1	0
Quiet garden	100	20
Quiet office	1,000	30
Average office	10,000	40
Vacuum cleaner	100,000	50
Busy street	1,000,000	60
Motor vehicle	10,000,000	70
Heavy street traffic	100,000,000	80
Underground railway	1,000,000,000	90
Boiler shop	10,000,000,000	100
Thunder	100,000,000,000	110

Measurements of this kind, however, have only a limited value, since they afford no information in respect of the frequency distribution of the noise. This is of particular importance, for example, in investigations of the masking effect of noise upon speech communication. Alternatively, a precise knowledge of the spectral composition of the noise of a machine may lead readily to the location and suppression of the noise from the offending components. For this purpose it is usual to subject the noise to some form of frequency analysis, provided the noise spectrum remains reasonably constant over a period of time.

The noise is picked up by a microphone, amplified and passed in turn through a number of filter circuits which break up the noise into a number of contiguous bands of frequency of from 5 to 100 cycles. The energy in each band can be measured on a meter or displayed upon a cathode ray oscilloscope.

The choice of the band width is determined by the amount of detailed information required. In certain noises, for example, a few intense components are present in a very narrow band of frequencies. A wide band analyser would indicate only the average energy over the band, and thus the selective nature of the component would be undetected. The narrower the band width, however, the more stringent are the requirements of the filters and, of course, the more tedious and time-consuming the complete analysis.

In the majority of problems a detailed analysis is unnecessary, and it is usual to use filters which break the spectrum, not into equal frequency bands, but into octave or 1/3 octave bands. In this way, the whole spectrum can be covered with as few as 8 octave band filters, and such analysis has now become common practice.

Typical octave band analyses of the noise in an average office, a living room with the windows open, and the Underground Railway are shown in Fig. 1. In general, however,

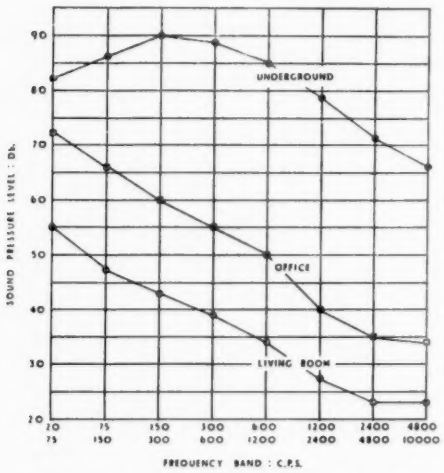

FIG. 1.—Octave band analysis of noise in (*a*) the Underground, (*b*) an office, (*c*) a living room. Adapted from the Handbook of Acoustic Noise Control, Vol. 1, Physical Acoustics, Wright Air Development Center Technical Report 52-204, with the permission of the Editors.

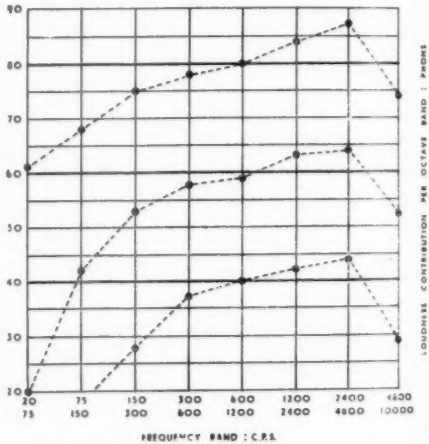

FIG. 2.—Computed loudness levels expressed in phons of noises with equal energy per octave at sound pressure levels of 40, 60 and 80 db.

we are interested in the loudness contribution each band makes to the overall noise level, and this information is not immediately apparent from such an analysis. This is exemplified in Fig. 2 which shows, by way of illustration, three flat curves drawn empirically at different intensity levels. The approximate loudness contribution in phons of each octave band is shown by the three interrupted curves.

The phon is a loudness unit defined in terms of the equivalent loudness of a 1,000 cycle tone. It enables the loudness of any pure tone or of any complex noise to be expressed in subjective units. The three loudness curves have been computed on this basis. Their dissimilarity to the intensity curves exemplifies the marked divergence between the subjective and objective attributes of noise. This is due to the fact that loudness is a non-linear function of both frequency and intensity, relationships which are illustrated in the well-known equal loudness contours shown in Fig. 3.

These were established by Fletcher and Munson (1933), and have for many years been the basis of most present-day psycho-physical computations. They differ, however, in certain respects from the more recent and comprehensive data of Dadson and Robinson at the National Physical Laboratory (1956).

The lowest curve is the threshold of hearing, while the upper curves express the intensities of tones at all frequencies which evoke equality of loudness with a tone of 1,000 cycles at the levels shown. These are, by definition, the loudness levels in phons.

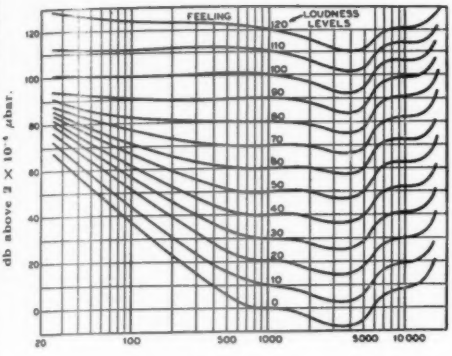

FIG. 3.—Sensitivity curves of the human ear (Fletcher-Munson).

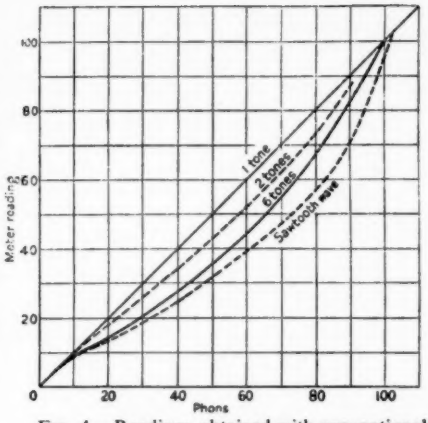

FIG. 4.—Readings obtained with conventional objective noise-meter, showing increase in error with number of components in noise. Reproduced by permission of the Editor of the *Journal of the Institution of Electrical Engineers* (Churcher and King, 1937).

The phon is a convenient unit because it provides us with a subjective scale which can be extended to any noise, however complex. Thus, the loudness level of a noise in phons may be determined by adjusting the intensity of a 1,000 cycle tone until it appears equal in loudness to the noise. The intensity of the 1,000 cycle tone in db. above the reference level 10^{-16} watts per sq. cm. is the loudness level of the noise in phons.

This procedure has obvious disadvantages. It is difficult and time-consuming. The observer must have "normal" hearing at all frequencies, and experience has shown that no two observers are likely to be in complete agreement. For these reasons, an obvious need has arisen for an instrument capable of providing objective measurements which match the subjective response of the perfect observer. Although a few highly specialized instruments have been developed, most commercial so-called sound level meters fall far short of this ideal. They can, however, provide useful measurements provided due regard is paid to their limitations and these will be considered as follows:

Let us suppose the sound level meter to be so designed that its frequency response followed the threshold sensitivity curve of the ear and further that with this instrument we now wish to record the loudness level of a 100 cycle tone 40 db. above threshold.

It will be seen from Fig. 3 that such a tone will have a loudness level of 70 phons, and this is far removed from the 40 db. it would in fact register. The reason for this is that at 100 cycles, loudness increases more rapidly with intensity than at 1,000 cycles. Such discrepancies would occur at all frequencies with the sole exception of 1,000 cycles which, by definition, would be a true reading in phons. The ideal sound level meter should be able to match the loudness function of the ear at all frequencies. Since this presents insuperable difficulties in design and construction, it has been the practice both here and in America to adopt a compromise. Frequency weighting networks are incorporated, by which the overall frequency characteristics may be adjusted to agree approximately with these equal loudness curves at certain chosen levels, usually 40, 70 and 100 db. If the level of the sound lies within the range 20 to 55 db., then the 40 db. network will be selected; 55 to 85 the 70 db. network, and 85 to 140 the 100 db. network.

If the sound to be measured is a single pure tone, the readings of the meter will provide a good approximation the noise level in phons. When, however, the sound to be measured is a complex one, as is usually the case, we are faced with a further serious difficulty.

If two or more tones are present, the conventional sound level meter will indicate the R.M.S. sum of their equivalent 1,000 cycle pressures. For example, if two tones of the same phon level are presented to the meter, the total sound intensity will be doubled, and its reading will be 3 db. higher than that which would be obtained if they were presented separately. Unfortunately, the ear does not sum loudness in this simple fashion. Two tones of moderate intensity and of equivalent loudness, separated by an octave in frequency, sound approximately 10 phons greater than the separate loudness of each. As the number of

tones increases this discrepancy increases, and for a multitone noise may be as much as 25 phons.

This effect is strikingly illustrated in Fig. 4 from a paper by Churcher and King (1937). This shows sound level meter readings for four different noises. One a single pure tone, one of two tones each of equivalent loudness, one of six pure tones each of equivalent loudness, and a saw-tooth wave. The loudness values in phons of each of these sounds have been computed, and are plotted along the abscissa. It will be seen that the departures of the meter readings from the true values are greatest at moderate intensities, and that as the number of components increases the inaccuracy of the instrument increases.

What then are the uses of an instrument which is capable of providing such fallacious readings? As long as due regard is paid to the fundamental defects described, and the results interpreted accordingly, they can provide valuable information, particularly in problems involving comparative measurements at different levels of either the same noise, or of noises of similar frequency spectra. A memorandum on the use of sound level meters compiled by the British Standards Institution (1948) stresses two points: firstly, that the noises to be compared must be substantially of the same composition, and secondly that the resulting measurements can validly only be expressed in sound level readings in decibels and not in phons.

The following investigation of the variation of voice level in the presence of noise of varying intensity will serve as a somewhat elementary example of the use of a sound level meter.

The experimental set-up is shown in Fig. 5.

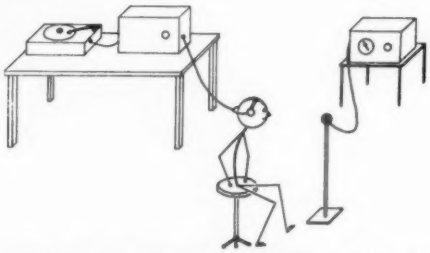

FIG. 5.—Experimental set-up for investigating variations of voice level in the presence of noise.

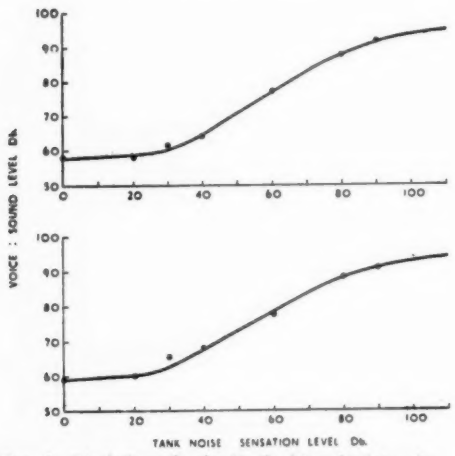

FIG. 6.—Variation of voice level with noise intensity.

The subject, a young adult with *normal hearing*, wears a pair of headphones connected by way of an attenuator calibrated in decibels to an amplifier and a gramophone pick-up. A record of a tank noise was used, and by varying the attenuator the subject's threshold to this

noise was first determined. The subject was asked to repeat six chosen words, and their level was recorded with a Western Electric sound level meter, the microphone of which was placed 3 ft. away from the speaker's mouth. The first measurements were made in the absence of any noise, and these were followed by a further series of measurements in which the level of the tank noise was raised in steps of 10 db. above the subject's threshold. Typical results from two of six similar subjects are shown in Fig. 6.

One of the most striking features revealed by these investigations was that in all six subjects, apart from some slight variation in level, the curves followed the same general course. As will be seen, the effect of noise upon voice level begins at the surprisingly low sensation level of 20 db. Thereafter, voice level increases linearly with noise until a maximum is reached at a noise sensation level of 90 db., at which point the voice appears to have reached the limit of its ability to match the noise.

Not the least surprising of our findings was the fact that, for any given noise level, the subjects were able, without any conscious effort, to maintain the level of their voices with great constancy, yet attempts to reproduce and to maintain the higher voice levels after the noise had been removed required very considerable conscious effort. It would seem that voice level is rigidly controlled by some central reflex mechanism analogous to the well-known principles of servo-mechanical control.

The phenomenon is worthy of special attention in studies of speech perception in noise. If recorded or monitored speech is used, the most serviceable data will be obtained only if the speech is delivered at a level found by experiment to be appropriate to that of the noise.

As an interesting corollary to these findings it will be seen that they provide firm support for the well-known theory propounded, by Jenkins among others, as long ago as 1913: that the phenomenon of paracusis Willisii arises in part, at any rate, from the fact that the hard of hearing subject benefits from the raised voice level of the normal hearing speaker in noisy surroundings.

The voice level measurements described represent a special case of a large body of sounds which fall into the category of transient sounds. Their measurement calls for special techniques, and these will be considered briefly as follows:

Impact and explosive noises give rise to very high peak pressures, which cannot normally be measured with a sound level meter owing to the inertial lag of the mechanical moving parts of the indicating instrument. To overcome this difficulty, an auxiliary instrument has been developed, termed a peak indicator, which is used in conjunction with the sound level meter.

The peak sound pressure develops a charge across a condenser incorporated in this instrument, and the detection of this charge by the sound level meter indicates the overall energy in the noise.

The spectral analysis of transient sounds is, of course, made particularly difficult by their brevity. If the noise to be measured has a minimum duration of a second or so, it can conveniently be recorded upon magnetic tape. The tape can then be made into a loop, and played back as many times as is necessary for an analysis to be carried out in the laboratory in one of the ways described for steady sounds.

The cathode ray oscilloscope lends itself particularly well to the spectral analysis of transients, since its response is free from the inertia effects to which reference has been made. Good use has been made of it in an instrument termed the acoustical spectroscope. The sound to be measured is amplified and applied in turn by means of a mechanical drive to each of a number of 1/3 octave band filters covering the whole of the audible frequency range. The output from each filter is displayed as a vertical band upon the face of the cathode ray tube, each frequency band being identified by an engraved scale immediately below the face of the tube. The whole spectrum can thus be sampled many times a second, resulting in an instantaneous picture of the spectral composition of the sound.

It has been the aim of this communication to outline some of the more important problems which confront the acoustical engineer, and it cannot be claimed that the field has been covered exhaustively.

Many problems remain; of these perhaps the most urgent are to be found in the overlapping fields of physics, psychology and physiology.

Professor W. Burns (Department of Physiology, Charing Cross Hospital Medical School):

Noise and Its Effects: Physiological Aspects

Introduction.—It is of interest that hearing loss from noise has been recognized at least since the latter part of the eighteenth century. Parry (1755–1822) describes cases (1825) which, at least superficially, conform to the characteristics of temporary and permanent hearing loss due to exposure to noise. In one incident, Admiral Lord Rodney is described as being almost entirely deaf for fourteen days following the firing of eighty broadsides from his ship, H.M.S. *Formidable*, in the year 1782. The other case is that of an officer who was stated to have been rendered permanently deaf by the near-by discharge of a cannon at the battle of Copenhagen. The problems of aural damage as a result of noise are still present, and in a much more acute form since those days; man-made noise has greatly increased in extent and in intensity, and it has become a problem of some urgency to study the relations between the noise and the effects by all available means, in order to control and minimize damage to hearing. The approach to this problem can broadly be made in three ways: the reaction to noise exposure of individual ears can be followed in practical situations by clinical methods, including that of pure-tone audiometry; the effects of specific noise stimulation can be studied in psycho-acoustic experiments; or stimulation of the ears of experimental animals may be preceded and followed by the use of some technique, psychological or physiological, which will detect changes in the response of the ear. Only the last method will be considered here.

Aural damage from sound.—Different types of hearing loss may affect the human ear as a result of sound stimulation. First, we may have temporary loss of various degrees of severity, which, at least, may be transitory and only detectable by special means or, at worst, may persist for hours or days. Greater severity of exposure to sound may produce permanent loss (usually combined with some degree of temporary loss) and this may arise from moderate sound levels, applied for months or years in the course of work, or from a single damaging exposure, such as a detonation or a very intense noise lasting for a period of the order of minutes or hours. These distinctions are of importance in the physiological approach, for some of these effects are more suitable than others for investigation by physiological means, as will be discussed later. In the present context only damage to the cochlea itself is considered; tympanic membrane and middle ear effects are ignored.

Physiological criteria of cochlear function.—In assessing the suitability of various physiological criteria as indications of the effect of noise on the ear, it is useful to recall some of the current beliefs on the fundamental features of cochlear function. The criteria relevant to this discussion are the electrical potentials known as the cochlear microphonic (CM) and the action potential of the auditory nerve (AP). In order to examine these phenomena in more detail it is desirable briefly to consider the movement of the basilar membrane when sound falls on the ear.

Movements of the basilar membrane.—Since the concept of Helmholtz, formulated in 1863, that the cochlea contained structures capable of resonating to different frequencies in a highly selective manner, some changes have occurred in our approach to the physics of cochlear function. The majority of current opinions regard the cochlea as a number of canals, partially bounded by elastic walls, in which wave motion akin to the pulse-wave in arteries is generated by movement of the stapes. A number of mathematical formulations have been built on these lines, varying in detail according to the assumptions made, but direct examination of the mode of vibration of the cochlear partition, i.e. basilar, tectorial and Reissner's membranes, has been made by Békésy (1949), using human cochleæ in suitably prepared temporal bones. This technique involves the replacement of the stapes by an electrically driven piston, which can be moved at known frequencies and amplitudes of vibration. The resultant movements of the cochlear partition are studied microscopically with stroboscopic illumination, through small windows in the bony wall, with precautions to ensure that the presence of the windows does not affect the result. These techniques showed that, in general, all the components of the cochlear partition, i.e. the basilar membrane, the organ of Corti, the tectorial membrane, and Reissner's membrane, vibrate in the same phase when the stapes vibrates. At frequencies of less than 50 c/s the entire cochlear partition vibrates at this frequency, and the vibration is practically in phase for the whole partition. At higher frequencies, travelling waves can be demonstrated, originating at the base of the cochlea, and travelling towards the apex. These waves increase in amplitude as they traverse the cochlea, finally reaching a maximum amplitude and then subsiding relatively suddenly, the maximum occurring at a distance from the base of the cochlea, characteristic of the particular frequency. The highest frequencies reach their maximum amplitude nearest the base of the cochlea, the waves due to lesser frequencies reaching progressively farther towards the apex before reaching their maximum. The relationships of frequency, phase, amplitude and

conduction velocity of the waves are complex, and are conveniently summarized by Békésy and Rosenblith (1951).

The cochlear microphonic.—It is now possible to obtain information about the action of the organ of Corti, and more indirectly about the movements of the basilar membrane, by a study of the cochlear microphonic, hereafter referred to as CM. This is an electrical potential which can be recorded, when sound reaches the ear, from a variety of sources in the cochlear region, for instance by an electrode placed on the round window and referred to an indifferent electrode on the neck of the animal. Much information has been obtained by a study of CM and its relations to sound stimuli (Stevens and Davis, 1938; Wever, 1949). The CM is found to resemble closely the sound stimulus applied to the ear, and thus is equivalent to the electrical output of a microphone. It does not resemble the potentials due to nerve activity, as is well known. It appears to be generated by the hair cells in response to movement of the organ of Corti, and particularly in the hands of Davis and his associates has become a very useful index of cochlear activity. Tasaki *et al.* (1952) have evolved a technique in which CM can be recorded simultaneously with the action potential of the auditory nerve, each electrically separated from the other. This technique employs very fine wire electrodes which are inserted into the canals of the cochlea; a pair of these electrodes can be used to obtain the potential across the cochlear partition by insertion into scala vestibuli and tympani of a particular turn of the cochlea. In this case CM can be recorded from a length of the cochlea in the order of 1 or 2 mm., so conferring an immense advantage over other methods because of the precise localization of function thus made possible.

By these means Tasaki *et al.* have shown that Békésy's conclusions, with regard to the action of the human cochlear partition when thrown into vibration by sound, can be confirmed for the guinea-pig cochlea. Thus, by examination of the amplitudes and phase relations of CM in two or more turns of the cochlea in response to various frequencies of sound stimulation, they demonstrated the occurrence of travelling waves which pass along the cochlea from base to apex, for a distance which is greater the lower the frequency of sound incident upon the ear. Their results only differ from those of Békésy on the movements of the human cochlear partition, in the apparently greater vibrational amplitude as judged by the voltage of CM in the basal regions of the cochlea. As in Békésy's mechanical study, the CM was little affected by deficiencies in the bony wall of the cochlea.

Of particular interest for the study of the effects of acoustic stimulation of the cochlea are the relationships of sound input to cochlear microphonic. Among the many complex relationships described by Tasaki *et al.*, an important one is the relation between sound pressure level of the sound stimulus and the voltage of the cochlear microphonic, measured at an appropriate part of the cochlea. The result is in conformity with earlier measurement of CM between the round window and an indifferent electrode placed on the neck of the animal, and shows that CM voltage is related linearly to the sound pressure levels, up to sound intensities at which CM either reaches a maximum and then declines, or else the waveform becomes too distorted for proper measurement. In addition, the "threshold" of CM can be determined for any particular frequency (Davis and associates, 1953); this is not the true threshold, but a sound level at which the presence of a recognizable CM waveform begins to be visible against the background oscillations of the output of the amplifying system. By utilizing this criterion a form of electrical audiogram of the guinea-pig ear may be obtained, but with the differential electrode system of Tasaki *et al.* the electrodes must, of course, be inserted into the part of the cochlea appropriate to the sound frequency used; for example, high frequencies will not produce CM voltages at the apex of the cochlea.

The action potential of the auditory nerve.—In the past, electrical changes due to the combined effect of the action potentials of all the active fibres in the auditory nerve, hereafter known as AP, were a feature of the classical round window records, and indeed of the original observations of Wever and Bray (1930), in which they appear combined with CM. By the differential method of recording, they can be separated from the CM oscillations, as stated above, and appear as a pure AP waveform, as if an electrode had been applied to the auditory nerve at the internal auditory meatus. In order to produce a well-marked action potential wave, by approximately synchronous activity in the active fibres, some form of brief acoustic stimulus is necessary. For this purpose a sound usually referred to as a click may be used; this is produced by applying a short square-wave electrical pulse to the coil of a loud-speaker. Alternatively, short duration pure tones, known as tone-pips, have been used by Davis and associates (1953), for the same purpose. When these are used, in records both from the round window or by the differential method, the "threshold" sound pressure may be determined for the ears of anæsthetized animals in acute experiments, again by presenting a series of acoustic stimuli at progressively increased intensity until AP is just visible on the oscillograph trace against the background oscillations. The size of AP will depend, among other factors, on the number of active fibres. The relationship between the stimulating

sound and the evoked nerve activity deserve, and are receiving, further attention at the present time.

Effect of efferent activity in the auditory nerve on the afferent output from the cochlea.—There is one other factor which may be of considerable importance in the interpretation of cochlear activity. Galambos (1956) has now shown beyond doubt that the afferent nerve discharge from the cochlea may be reduced or inhibited by electrical stimulation of the medulla; and moreover, that the effect appears to be mediated through the olivo-cochlear bundle described by Rasmussen (1946). These results were obtained by presenting click stimuli to the ear of the decerebrate or anæsthetized cat, and recording the electrical activity so caused from the round window. The electrical output contains both CM and AP, and it is noteworthy that, although AP may be reduced or abolished by stimulations of the medulla, the size of CM is unchanged. The great potential importance of these phenomena need not be emphasized, and it is of interest to note that there are other sense organs whose sensitivity is not invariable, but adjustable through the operation of pathways carrying efferent impulses from the central parts of the nervous system; such a system is of great importance, for instance, in the control of skeletal muscle, by discharge from muscle spindles.

Indices of cochlear function following intense sound.—Having looked briefly at the phenomena which are potentially useful in a physiological approach to the study of the effects of intense sound on the ear, we may now consider how they may be used for this purpose. The basic operation is to determine certain characteristics of the normal ear, to subject it to sound stimulation, and then to repeat the initial observations. As a result of work of this sort, as described by Wever (1949) and by Davis and associates (1953) it has become evident that the type of electrical index must be appropriate to the type of sound exposures used. For severe or damaging exposures, CM provides a useful guide, due to the fact that severe exposures are required to produce appreciable reductions in CM voltage. It may with advantage be used in conjunction with histological examination of the exposed cochlea. On the other hand, for the study of transient effects following less intense stimulation, and corresponding to temporary hearing losses, the more sensitive and labile AP provides a more suitable index, and has been so used by Rosenblith *et al.* (1950), by Rosenblith (1950) and by Davis and associates (1953), and by others. These techniques may now be examined in greater detail.

The cochlear microphonic as an index of acoustic trauma.—The differential recording system of Tasaki *et al.* is admirably suited to an examination of the local effects of intense stimulation by pure tones, and this has been combined with histological examination of the cochleæ of guinea-pigs so exposed, by Davis and associates (1953). It is well to emphasize again that the electrode position must be appropriate to the frequency of sound stimulation in order to assess changes of CM following such stimulation. It is not possible in the scope of this brief review to cover adequately the details of this work, but the essential findings showed that CM is a reliable index of damage to the cochlea. It was found that, following sound stimulations, the "threshold" of CM was elevated in terms of db., by twice the amount of the reduction in "maximum" voltage of CM, produced by an arbitrary high level of sound stimulation. The extent of these reductions was compared with an arbitrary numerical scale describing the observed degree of damage to hair cells and supporting structures in the cochlea. The effects ranged from minor changes in the cellular structure to gross disruption, breakage and displacement, and it was found that the extent of change of CM voltage or threshold was consistently related to the numerical scale of damage. The injuries caused by tones of 8,000 c/s centred in the basal turn, 2,000 c/s in the second, 545 c/s in the third and 185 c/s tones at the junction of the third and fourth turns; no pure tones at these frequencies and at intensities up to 148 db., and durations of the order of 5 minutes or less, damaged the entire cochlea. It was also found at the highest intensities (about 144 db. at the eardrum) that an exposure to one minute at any of the four frequencies used produced equal degrees of cochlear damage. In assessing the probable implications of these results for the human ear, the authors believe that the human ear is similar in strength and resistance to damage to that of the guinea-pig and in general that for given amplitudes of the stapes in the oval window, it could probably be assumed that the damage to human ears would be similar to that found in the guinea-pig ears, except at the lowest frequencies, where the intra-aural reflex may give appreciable protection in man.

Auditory nerve action potential as an index.—For the study of transitory after-effects of sound upon the ear AP may be elicited by brief test stimuli such as clicks at some arbitrary sound level, in the manner just described; following this, the fatiguing tone or noise is applied, and the test stimuli resumed at the same intensity as before. The "threshold" of the ear may be determined on the basis of a just visible AP, or the effect of the fatiguing tone followed by using the amplitude of the AP wave as an indication of the neural activity. Rosenblith *et al.* (1950) have employed such means in the cat, using click stimuli and recording

the combined CM and AP from the round window. It was found that exposure to loud tones reduced the size of AP immediately after the fatiguing tone, and that the rate and mode of recovery depended on the intensity, the frequency and the duration of the fatiguing tone. During these changes in AP, CM shows relatively little change. Rosenblith (1950) describes further applications of this technique; the recovery rate of AP can be quantified by expressing the size of the post-exposure waveform as a percentage of the pre-exposure size, which permits the construction of a graph of recovery of AP as a function of time after the end of the fatiguing tone. If this method has any similarity to psycho-acoustic experiments on the recovery from temporary hearing loss, one would expect a restoration of the pre-exposure characteristics of AP in a period of the order of minutes after moderate exposures, and this is indeed found to be so. Further, the exposure to click stimuli would appear to indicate that the temporary impairment is more severe when the test stimuli (clicks) are weak, than when they are presented at a high intensity. In the latter case little or no reduction in size of AP may be found, and this provides an interesting comparison with the situation in human deafness in which recruitment is present, and in the work of Davis *et al.* (1950) whose experimental exposure to loud tones or noise was followed by a much greater depression of the threshold sensitivity than of the apparent loudness of tones.

These illustrations indicate the lines along which investigation may be pursued. The basic need at present is to provide a better understanding of the physiological processes underlying the reaction of the human ear following various kinds of acoustic stimulus. Enough is known to enjoin great caution in comparing the situations involved in acute acoustic trauma, long-term hearing loss of the occupational sort, and temporary hearing loss. As Davis and associates (1953) point out, and the same is true at this time, our knowledge of the physiological processes involved is still insufficient to justify theoretically the use of some test of temporary hearing loss, as an indication of susceptibility to long-term industrial permanent hearing loss. Work continues in these fields, however, and one may anticipate further elucidation of the basic physiological reactions to sounds which, in one way or another, may be potentially damaging to the functional integrity of the ear.

Mr. D. E. Broadbent (Applied Psychology Research Unit, Cambridge):

Noise and Behaviour

There are three kinds of psychological experiment to be discussed in this paper: that is, three kinds of experiment on the behaviour of intact human beings. The first kind is really an extension of physiology, because it is aimed at finding how much a man's hearing has been damaged by noise. Instead of examining the damaged tissues in the ear directly, however, the method is to study the effects in behaviour: in other words, the change in the threshold of hearing. The second kind of experiment to be mentioned will be researches on the way in which speech perception is affected by losing hearing in particular frequency bands, which is a common effect of noise exposure. The third group of experiments will be those on the efficiency of work in noise, which is more nearly what is usually meant by a psychological effect.

To start with the question of deafness, most of us are not surprised when a man who announces himself as a boilermaker or an artilleryman, proves to have a poor audiogram. This kind of common-sense impression is a little dangerous, perhaps; because a man with a history of years of work in noisy places has to be fairly old. People do get more deaf as they get older, and so one must beware in case one's clinical impression is comparing boiler-makers of 50 with sprightly young apprentices of 18. The average man of 50 has in any case lost 20 db. at 4,000 c/s, according to several large-scale surveys.

But there are now a number of researches which have allowed for age and which have demonstrated that people with noisy work can hear less than people of the same age with

quiet work. For instance, Guild (1951), showed that U.S. Air Force aircraft mechanics had poorer hearing than members of the Air Force who worked in comparatively quiet places. Out of men in the 25–29 group, less than half the mechanics had normal hearing, or only slight loss, while amongst men of the same age working in quiet, over 80% were normal. In this country, Johnston (1953) studied seven kinds of work having different noise levels, and found an increase in the proportion of people with hearing loss as the noise increased, provided the people had at least twenty years' exposure to the noise. Hearing loss in this case was detected by requiring the patient to understand speech at 3 feet distance which is hardly a sensitive test. It makes the finding that 9 out of 12 workers in the worst noise had a hearing loss by this test, rather an alarming one. Their loss was really noticeable.

But these rather general investigations do little more than confirm our original opinion that deafness due to noise is of practical importance, and is not simply an effect which laboratory researchers play with for want of something better to do. Given that the effect is important in practice, we want to know what frequencies are dangerous and how loud the noise has to be to produce deafness. Some data on this have at last become available, thanks to the American Standards Association (1954); and in particular to their Subcommittee which rejoices in the title of Z24X2. Dr. Wayne Rudmose, on behalf of this Subcommittee, visited a number of factories and took 7,000 audiograms from the workers. He then examined those cases in which the intensity and spectra of the noise were known, the length of exposure to the noise was known, and the worker was not known to have been exposed to any other loud noise. This cut the 7,000 down to 200, which is, of course, why nobody had done research of comparable scope previously.

Two hundred people are sufficient for certain valuable conclusions. For instance, one can correlate deafness at a particular frequency with noise exposure at that frequency, or at frequencies one octave lower or higher, two octaves and so on. If one does this one finds that deafness at 4,000 c/s doesn't seem to be closely related to the amount of noise of 300 c/s to which the individual has been subjected. The best predictor of deafness at 4,000 c/s is the amount of noise in the octave from 1,200 to 2,400. Correspondingly the best predictor of deafness at 1,000 c/s is the amount of noise in the octave from 300 to 600. In other words, noise of a particular frequency seems to be related to deafness at a slightly higher frequency. This agrees with laboratory experiments on temporary deafness, in which at high intensities the deafness shifts upwards in frequency from the stimulus frequency to a higher one.

At the same time, it is still true that the 4,000 c/s region is more easily affected by noise. If you have worked for ten years in a noise having 88 db. in the octave centred on 1,800 c/s, your hearing at 4,000 c/s will be almost 25 db. down (on the average). If you had had a comparable exposure in the octave centred on 450 c/s, your hearing at 1,000 c/s would be only 5 db. down. If you want to keep the noise down to the point at which the loss of hearing as the years go by is merely the average for the community at large, then you can have 80 db. in the octave centred on 450 c/s, but only 73 db. in the octave centred on 1,800 c/s. In summary, the 4,000 c/s region is definitely more susceptible to noise, but deafness to a particular frequency is largely a question of exposure to noise of a particular frequency band rather below that at which the deafness occurs. Measuring simply the total level of a noise tells us very little about its deafening qualities: the spectrum is also necessary.

The safe levels per octave which I mentioned earlier are very low: many industrial processes exceed them. It would be very valuable if one could pick out the tenderest ears from a group of workers before they were damaged, so that the remaining people could work in a rather higher level. A start has been made in this problem by Jerger and Carhart (1956) who measured temporary deafness from a one-minute exposure on a group of people who afterwards worked in jet-engine noise for a period which exposed them to the risk of permanent deafness. The people who had the biggest temporary deafness were, on the whole, the ones who afterwards suffered the greatest permanent harm. Unfortunately, the relationship was not as close as one would like, some people with a small permanent loss having had a large temporary one; this may be because the permanent deafness was not in any case very considerable, or possibly because of some particular feature of the technique of measuring temporary deafness. After being temporarily deafened, the victim had to listen until he recovered enough to hear a pulsed tone of standard intensity: which often meant listening for ten or fifteen seconds before responding. It may be that wandering of attention would introduce a random element into the results of such a test which would not be present in other techniques. In any case, the possibility of using deliberately produced temporary deafness to pick out susceptible people is one which is well worth pursuing.

Now, what effect does this type of deafness have on speech perception? Nobody seems to have studied the kind of mistakes which are made by people with certain kinds of deafness, but there is a good deal of recent information about the effects on speech of various kinds of distorting telephone line, and these seem to be rather relevant. Admittedly the kind of deafness produced by noise is not simply a removal of the ability to hear high frequencies,

since there is also a distortion of the loudness of sounds which are intense enough to be audible. Still, the effects of removing high frequencies from a telephone circuit are likely to have some similarity to those of deafening a man to high frequencies while leaving the lower ones unimpaired. And noise, as we have seen, does produce rather that effect.

If we consider the consonants usually written as p, t, and k, we find that they are produced in the same sort of way but in different parts of the mouth. P as in "pen" is in the front, t as in "ten" farther back, and k as in "ken" farther back still. This difference in the place of articulation produces a difference in the sound, so that a listener can tell which consonant has been said. The same kind of difference exists between b, d and g, between f, s and sh, between v, z and j, and between m, n and ng (I use ordinary letters although really phonetic symbols would be more accurate). Now how do we tell the difference between these groups, since the place of articulation distinguishes only within them? How do we tell p from b, or f from v? Well, in b and v the vocal chords vibrate while in p and f they do not: the consonants are said to be voiced and unvoiced correspondingly. And the difference between b and v, or between p and f, consists of the presence or absence of fricative noise. Consonants can therefore be placed in an interlocking classification, and it has recently been shown by Miller and Nicely (1955) that removing the high frequencies from speech affects chiefly the discrimination of place of articulation. The presence or absence of fricative noise is more easily distinguished, and the occurrence of voicing is the least affected by losing the high frequencies. The words "pat" and "bat" for instance, can be distinguished using low-frequency hearing, but the distinction between such words as "pop" and "tot" requires high-frequency hearing (Table I).

TABLE I.—DISTINCTIONS BETWEEN CONSONANTS

	No fricative noise	Fricative noise
Unvoiced..	PTK	FS SH
Voiced ..	BDG	VZ J

Consonants within each cell differ in place of articulation and are likely to be confused by people relying on low-frequency hearing. Confusions between right and left, and particularly between upper and lower cells, are unlikely. Ordinary consonants are used for expository purposes: phonetic symbols would be more accurate.

There is hardly time to go into it, but the work of F. S. Cooper and his associates (1952), using artificially generated speech sounds, gives some explanation for this finding of Miller and Nicely. Crudely, when one makes a vowel such as "ar" in "par" or "tar", at the very beginning of the vowel one's tongue has to rush across the mouth in a way which depends on the place at which the previous consonant was articulated. This means that the very beginning of the upper harmonics of the vowel are different when the preceding consonant is a p from those which follow a t. The difference is rather a high-frequency one, while the effect of voicing is to introduce a low-frequency component which is particularly difficult to mask. Yet whatever the explanation, the practical importance of these findings is that people deafened to certain frequencies by noise exposure are likely to have rather specific difficulties in understanding speech: some statements they will understand perfectly. And, as Miller and Nicely point out, the place of articulation which is the most likely feature of consonants to cause difficulty, is the easiest feature to detect by lip-reading. As a result the advantages of lip-reading to the noise-deafened will be greater than one might imagine at first sight.

In considering the effects of noise on behaviour which does not involve hearing, we should distinguish annoyance by noise from a direct effect on efficiency. Annoyance often results from some feature of the individual's past experience. For instance, in a recent survey of complaints about aircraft noise, it was found that over 80% of the people who complained had some reported anxiety about aeroplanes—they would not fly themselves, or they were frightened of aircraft crashing on the house (C.H.A.B.A., 1954). One can make rough rules, such as that the proportion of people who are annoyed will rise as the noise becomes louder, or that a noise which seems to be preventable will produce more complaints than one which is normally regarded as inevitable. But the reduction of annoyance remains rather an empirical art.

Until recently it was thought likely that the only effect of noise on working efficiency was the indirect one that it might irritate and annoy the workers, a matter which could perhaps, if necessary, be countered by higher pay or a better canteen. But it now seems established that particular kinds of work are affected in a particular way by noise, even though other kinds of work may not be. There are two effects which have been shown. First, if a man is watching for some rather insignificant event to happen, such as a faint spot of light to appear in a gun-sight, and if he does not know when this event is going to occur, he will take longer to respond to it when working in a noise. Second, in a very continuous task allowing no breaks for rest, momentary errors and aberrations will occur in noise although work between these errors will be quite unaffected. For instance, if one is keeping count of three streams of parts going past on three conveyor belts and must take action every time ten parts have gone by on any particular belt, one is likely to make some mistakes in noise.

Both these effects will only appear if one has been working for some time in the noise. These effects were originally somewhat doubtful, resting on one group of experiments done in a Cambridge laboratory (Broadbent, 1953, 1954), but they have now been confirmed by two research centres on the other side of the Atlantic, which makes them more universal in their application. The task for keeping count of several streams of events was devised by H. J. Jerison (1954) working for the U.S. Air Force. The American workers have also pointed out the interesting fact that judgments of time-intervals are very badly distorted by noise (Smith *et al.*, 1955). None of these effects has been shown with noises of less than 90 db.

Now why do these rather specific effects appear although noise produces no effect on, for instance, the time taken to sort cards or the score on an intelligence test? I personally find it helpful to draw an analogy with the familiar process of blinking. Every time you blink you produce an interruption of the flow of visual information into your brain. Yet the interruption is a short one, and in any case blinking can be suspended while one does a *short* job requiring close attention, the necessary blinks being made at some other time when nothing is likely to happen. For instance, it is known that a driver blinks less in heavy traffic than on the open road. And in addition, work on familiar tasks can often be done without taking in information at all; a real yachtsman can tie knots on a dark night with his fingers numbed with cold. Blinking, therefore, scarcely affects the efficiency of work.

I think myself that there is a process like blinking but located between the sense-organs and the main body of the nervous system, and producing interruptions of the flow of incoming information which last perhaps a second rather than the small fraction of a second taken by true blinks. These internal blinks are supposed to be increased in frequency by noise, and they would produce just the effects on behaviour which are in fact observed. There would be no effect on short tasks nor on those which contain periods in which the worker knows that nothing will happen. But there would be a delay in noticing unexpected events, and there would be momentary errors in responding to a truly continuous stream of stimuli. There is a good deal of supporting evidence for his view. To take a physiological, though indirect, example, it has been claimed by Hernández-Péon and his associates (1956) that the usual cochlear nucleus response to click sounds disappears when the cat from which recordings are taken is shown a mouse. This is exactly the sort of mechanism which I have called an "internal blink". The kind of work likely to be affected by noise is the kind which would be affected by blinks if each blink lasted a second. Very often this means that accidents and scrappage rather than output will be the danger sign in industrial situations.

All this recent knowledge about noise warns us, in fact, that we must not be provoked by the overstatements of those who find noise annoying, into denying that it affects human beings. It does do so, to a limited and increasingly well-understood extent, and we should guard against it.

[*November* 7, 1956]

Medicine and Dentistry in Newcastle Upon Tyne in the Eighteenth Century

By JOHN BOYES, F.R.C.S.Ed.

Professor of Oral Surgery, University of Durham

NEWCASTLE is an old town by most standards of antiquity with a long and fascinating history and there are still places of great charm to remind us of former days. The castle and St. Nicholas' Cathedral with the beautiful lantern tower are the best known.

The Company of Barber Surgeons of Newcastle upon Tyne is another link with mediæval times. Unhappily its membership has dwindled to a handful and it is almost certainly destined for extinction despite the valiant attempts to resuscitate it by Professor F. C. Pybus and the late Professor Grey Turner. This is the oldest Newcastle Medical Institution and Newcastle and London are the only towns in the country where such a Company still exists.

The activities of the Barber Surgeons Company in the 18th century were quite varied. In addition to the particular matters affecting the Surgeons they contributed generously to a number of local and distant charities; for instance in 1740 they sent 10 guineas to the Edinburgh Infirmary. Part of the enjoyment of historical enquiry is the occasion which it affords for speculation. The explanation of this donation is probably the wide appeal which was made at that time on behalf of the Edinburgh Infirmary. (The success of the appeal enabled the Infirmary to be accommodated in a new building the following year.) However, on searching through the Newcastle papers in the 1720s I noticed annually for a number of years the announcement of the commencement of the Medical Course in the College in Edinburgh, and I wondered if some of the surgeons of the Company had gone to Edinburgh and studied surgery and anatomy under Alexander Monro primus and thereby had a partiality for Edinburgh medicine.

During the serious corn riots of 1740 the surgeons of Newcastle took turn to be on civic guard. By a majority vote they offered their Hall to the town during the active military preparations at the time of the '45. It was thought that the Hall would provide adequate accommodation for officers. As dissections were done in the Barber Surgeons' Hall, one imagines it was rather a grim place in which to be billeted.

In 1758 Richard Lambert, surgeon to the Infirmary, announced that he would begin a course of Anatomical and Chirurgical lectures at the Surgeons' Hall, Newcastle. I do not know if this course was ever held as it was never advertised again. Dr. Wilson gave a course of lectures in Medicine in 1767 at his own house in Rosemary Lane.

In 1724 William Prior, a musical instrument maker, moved from Gateshead to Newcastle and in a house at the head of the Side, set up business and designated his trade by signing his shop with a musical instrument. Ten years later he organized a raffle: "On Tuesday, 22nd October 1734 next at the house of William Prior there will be raffled for a new organ, concert pitch, fit for church, chapel or chamber, with two sets of keys, long eights and eight stops, viz: open diapason, stop diapason, principle, flute, 15th, cornet, sesque alto and trumpet so contained that four of the said stops with proper handles all are played upon the lower set of keys and for greater variety several of the stops draw in halves. There will be 100 lots or no raffle. Price of each lot to subscribers, one guinea.

The said organ may be on view every day till the time of the raffle begins at Mr. riors which will be at 1.0 o'clock in the afternoon of the aforesaid day."

However, it is his 1724 announcement that is of interest. In it he states that h sells all types of musical and mathematical instruments, music books of tunes and song and he does turning work at reasonable rates, and then the important thing—"he also makes and sets artificial teeth so neatly as not to be discovered from natural ones". Fifteen years later William Prior advertised in the first number of the *Newcastle Journal* which was published on April 7, 1739, and this time his advertisement was largely dental.

"Artificial teeth set in so firm as to eat with them and so exact as not to be distinguished from natural. They need not be taken out at night as is by some falsely suggested but may be worn years together. They are so fitted as to be taken out and put in at pleasure by the person who wears them and are an ornament to the mouth and greatly helpful to the speech. Also musical and mathematical instruments are made and all sorts of turning done by William Prior at Whitefriars at the foot of Westgate, Newcastle."

The medical advertisements in the early press are of interest and give some indication of common ailments. In 1721 we find Tipping's Pleasant Liquor advertised. This "dissolves the stone in the bladder or kidneys, bringing it away visibly with whatever gravel may be generated in those parts and gives ease in the colic as likewise the pains of the gout and rheumatism and soon after restores the use of limbs and is only sold at Harrison's Coffee House at the Sandhill, in Newcastle at 3/6d. a bottle". Again, there is The Most Excellent Cephalic Water or Liquid Snuff which was prepared for her late Majesty Queen Mary and published "by her authority". "It is the brain's best friend in curing all its diseases as all violent headaches, apoplexies, epilepsies, migranes, vertigos and swimmings in the head etc., price 6d. per bottle."

I wonder what the citizens of Newcastle thought on reading in 1720 "whereas many thousands die yearly of worms only, more than any other distemper whatsoever, and as all persons of all ages are incident to them even from birth to old age and as they are the inlet of most distempers and as Dr. Lucas' remedies of Newcastle have been tried and found by the experience of many hundreds to exceed any others yet known for killing and destroying of worms and the cause thereof in old and young and has never yet failed in its designed end by bringing away worms of various sizes and shape some from children of six or seven years old and upwards of 7 yards long at the Doctor's house to be seen. The medicines are as pleasant as sugar candy and as safe as white bread. They may be given to a child of three months old. Also for the further good of mankind is published the doctor's chemical preparation for killing the toothache without drawing, and scurvy in the gums by giving immediate ease in the most tormenting pains and carrying off the sharp humour which falls from the teeth and gums. Also it fastens loose teeth and causes the gums to grow afresh although eaten away with the very scurvy and those who use it are seldom or never troubled with the toothache any more where it is applied, so that a person may by these methods preserve all their teeth fair and sound even to an old age, price 1s. 0d. a bottle with full directions, sold at the Doctor's house in Pilgrim Street, in Newcastle over against Silver Street end, a ball being over the door where may be had his powder for the stone and gravel, strangury and stoppage of the urine, also his tincture of gold that cures rheumatism and weakness in the body or limbs".

Dr. Lucas died in 1720, a few weeks after the publication of the advertisement just quoted, but his wife was in the secret for she says: "These are to acquaint the public that the doctor faithfully communicated every secret of his medical preparations to his spouse who had upwards of ten years' experience in their preparation" and she goes on to say that "the preparations are just the same as if the doctor were now living."

In the edition of the *Newcastle Courant* of February 9, 1723, there can be read the following: "Whereas the smallpox and very dangerous sort of fever have for a considerable time raged with much violence in the town of Newcastle upon Tyne and other neighbouring towns and has been attended with great mortality, this is to give notice that there is a medium discovered which after immense trials has never been known to fail of curing persons afflicted with either of these fatal distempers, even when all other means used for their recovery have proved ineffectual and very often when they have been in all appearances at the last gasp and given over by those who have attended them, which medicine was discovered and now prepared only by Mr. Thorauld, master of mathematics and student in physick next door to the Mayor's house in Newcastle aforesaid. This wonderful medicine being known to no other person living and never before made public but now advertised for the general good of mankind at the pressing instance and request of several of the principal inhabitants of the said town who have seen and experienced the surprising effects thereof."

Accidents of severity are reported from time to time in the papers. For instance in October 1724 "about 7.0 o'clock in the evening, a fire broke out in the house of Joseph Partis, merchant, which burnt down that part of it by the great church and the neighbouring houses were in the utmost danger but saved by the great care and vigilance of the Right Worshipful William Carr Esq., Mayor and other of our Magistrates, but the most dreadful accident in the conclusion by a quantity of gunpowder which had lain in the garret and the people having no notice of it, it took fire when part of the house was blown up and several men and women were killed upon the spot. Others have died since of their wounds and a great many labour under great uneasiness occasioned by this fatal blast. The cries and shouts of the people were scarce to be endured which continued about an hour, women running as distracted seeking for their husbands, children etc., and everyone seemed to be in the utmost confusion. The Mayor and several of the Aldermen were hurt and were in great hazard who having ordered the surgeons to take care of the several persons who are wounded and given £50 as a reward to those who were most diligent and active in extinguishing the fire". Newcastle employed a town surgeon who was paid £50 per annum but it is obvious that he alone could not cope with an accident of such magnitude.

Another well-remembered accident occurred in October 1750. It was reported as follows in the *Courant:* "On Saturday last in the afternoon as the Leed's wagon was going down the Side, the wheel chain broke which caused it to run with great swiftness and notwithstanding all possible precautions taken by the waggoner to prevent mischief, one Barbara Saunders wife of a nailor at Dunston was run over by which one of her legs was sore shattered and she was otherwise very much bruised. Soon after the accident her leg was cut off and we hear there are hopes of recovery." This accident was used in B.K.'s famous letter of December 28, 1750, and published in the *Newcastle Courant* January 6, 1751, which appealed for the establishment of a hospital to deal with injuries and sickness in the people of Newcastle, Northumberland and Durham. Here is his account of the accident:

"There was the case of that poor woman who had the misfortune but the other day to be run over by the Leed's wagon and whom I am told lay 5 or 6 hours in an open shop in the utmost misery and anguish before a lodging could be found for her or any assistance given her." B.K.'s letter met with an immediate response and public activity on behalf of the new hospital was most energetic. Subscriptions poured in as did offers of gifts in kind and of professional services. The gifts in kind included bed linen, crockery, bricks for building the hospital and a quantity of lime; free professional services were offered by the Physicians and Surgeons; there were also given the proceeds from musical concerts and theatre performances. Within a period of less than five months the hospital was opened on May 23, 1751, in temporary accommodation in a house in a street called the Gallowgate, just outside the town wall. The day when the hospital was opened was one of the most important in the history of the town. The Magistrates and Council and all the prominent people of the town and of the two counties attended a service at St. Nicholas' Cathedral at 9.30 in the morning and thereafter walked in procession up the Bigg Market, along Newgate Street and through the New Gate to the hospital, and after an inspection watched the examination and admission of patients.

The history of the Infirmary has been so well told by Professor G. H. Hume and by Sir William Hume that little further need be said except to mention one of the intriguing problems of medical history in Newcastle which is, where is the exact location of this house in the Gallowgate? There would seem to be no doubt from contemporary maps that it must have been on the north-east side of the street and probably close to the New Gate. We know something of the house itself for in the house visitors' report of July 18, 1751, there is a recommendation that each ward should have a Bible, a Book of Common Prayer and the Whole Duty of Man. As the result of this recommendation six Bibles and six prayer books were bought forthwith. This would seem to indicate that there were six wards. Further confirmation of this supposition has also been found. When the Infirmary removed from the Gallowgate to the permanent buildings which were built on the Forth Banks, in October 1753, the house was rented to Mr. George Dunn of Blaydon. Early in January 1754 Mr. Dunn advertised as follows:

"To lett. The front part of the late Infirmary in Gallowgate consisting of six fire rooms, a cellar, with water in the yard and other conveniences. For further particulars inquire of George Dunn at his house in Gallowgate who will lett the same."

Through the kindness of the present owners of the property in the vicinity of the New Gate—Messrs. Scott and Turner—I have examined the old documents of the property but there is no trace of Mr. Wastell's ownership and he was the owner of the house which the Governors of the Infirmary rented. So the quest still has to be continued.

A house in the Gallowgate also was used for the first hospital in Newcastle for lunatics in 1763. Again, this house is unknown. The lunatic hospital was established as a result of a letter by "Benevolus", published in the *Newcastle Journal*. After a short period this institution moved to a specially built hospital nearby in Wardens Close. The surge in public opinion for the establishment of adequate medical services was by no means halted and soon afterwards St. Luke's Hospital for Lunatics was established for private patients. Before this the Lying-in Hospital was established in Rosemary Lane. The Newcastle Dispensary offering out-patient facilities was established in 1777 and a Society for helping poor expectant mothers in their own homes was founded a year or two earlier. A prominent worker for this Society was William Smith, surgeon and man-midwife. He was one of the medical staff of the Society. For many years Smith conducted courses of lectures and clinical practice in midwifery in Newcastle; the first, in which he was associated with Mr. Greenwell, was advertised to take place in 1756 at Mr. Greenwell's house, Without Newgate.

The mention of midwifery takes us easily, if perhaps surprisingly, to vaccination, for in the *Journal* of June 4, 1768, we read "Beatrice Macdonald, midwife, will begin a course of lectures on vaccination on Monday in the Race Week in the forenoon at her house in the Sandgate. Such as are now practicing or purpose to practice innoculation may by application to me be supplied with my preparation for the same which the faculty may be assured has been administered to thousands with never failing success, and far exceeds the pompus suttoniam of any other arcana in speedily and effectively removing every disagreeable symptom which may appear during the whole process of the disease, and am certain had they been administered even when a very putrid smallpox raged they would have been attended with success. N.B. Such of the advertising parties as have not been instructed with the care of a single patient will be instructed privately and immediately admitted into practice on the most reasonable terms. The poor in the neighbourhood of Sandgate innoculated gratis."

While smallpox inoculation was popular in 1768 it had been in the news much earlier. In September 1721 there is an account in the "News from London" column of the *Courant* of Mr. Maitland, the surgeon, inoculating for smallpox six criminals at Newgate Prison. "It has succeeded on the five who never before had them beyond all expectation and the surprise of the Physician who almost every day visited them. The sixth who had them about last Michaelmas in Newgate found no matter of alterations, the innoculations in his arms and legs continuing pale and dry from the beginning so that the whole has most successfully answered Dr. Timony's account of this practice and is perfectly agreeable to the experience and observations of some persons now in London of known credit and reputation who have seen the practice in Turkey. The malefactors on whom the experiment was made are to be soon pardoned."

Inoculation for smallpox again was news in 1723 when the local paper intimated that Mr. Ammand, a noted surgeon, inoculated the smallpox at Leicester House upon the young Prince William Augustus aged 2 years and 1 month.

We find an early intimation of a fever that raged throughout England in 1733. "Whereas the present distemper appearing in the shape of colds, agues and fevers rages so violently in every family within the bounds of mortality and in most counties in England, these are to certify the public that the most effectual medicine recommended by the most eminent physicians that has yet been experienced for same is Daffey's Original Elixir to be had from the printer of this paper."

The fever or the 'flu, whatever it was that struck this country as an epidemic, was severe. The London correspondent of the Newcastle paper reports that on February 1, 1733, "1,588 people died in London in a week, the greatest number known since the sickness in the year 1665, but it seems that infants and aged people suffered most". This epidemic also raged in Edinburgh about the same period, and the Newcastle paper quoted its Edinburgh correspondent as saying "A sickness continues here and in all the country around, so that scarce a family has escaped. It is attributed to the unwholesomeness of the weather there having been little frost and almost no snow at this season". Later in the same year there were great rain storms of unprecedented severity in South Scotland and the North of England. Even in the eighteenth century the weather was blamed for a great deal of their troubles.

There was plenty of rain and snow in January 1740—here is the account as published: "January 1740 the greatest storm of easterly wind and snow that can be remembered the violence of which did vast damage upon the river Tyne by vessels running foul of each other and breaking of cables and pulling the rings out of the ground. Upwards of 40 keels broke from their moorings and by the force of the wind were drove up to the bridge and sunk several wherrys, ships bows staving each other. . . . The same day in the evening

a woman going home to Gateshead Fell was found next day dead among the snow occasioned by her falling into a ditch where there was 7 ft. of snow." Unemployed keelmen were engaged by the Mayor to clear the streets of snow and Alderman Ridley "gave heaps of small coal to all poor people who could fetch them". A great number of poor families in Sandgate and other places were thought to have starved in the extreme cold. The Churchwardens of All Saints provided "plentiful dinners to the poor of the parish at the Manor House". "A pheasant was frozen to the ground near the town." We hear from Penrith that "a poor man was found lying upon the snow near that town, being carried into the town was let blood and that instant died".

Leaving the cold and snow let us move on twenty years to discover that in the pleasant autumn of 1760 "Michael Whitlock, operator for the teeth is at the Queen's Head, Mr. Hay's in Durham who intends to be at Newcastle on Sunday 28th September and to continue one week, and to be at Durham the week following and so to continue week about at both places. He is well known in most parts of England and Ireland for his extraordinary art in fixing artificial teeth in so exquisite and beautiful a manner as has baffled the most distinguishing penetration and of equal use in every respect. He cleans the blackest and foulest teeth in a few minutes rendering them as white as ivory, restoring the mouth to its wonted sweetness without pain. He dexterously displaces teeth and draws stumps almost imperceptibly so sunk within the gums that no other artist would attempt".

Fourteen years later another dentist, Charles Edward Whitlock, came to Newcastle and set up in practice in Newgate Street. He was perhaps the first semi-permanent dentist for I have not been able to find any other trace of Michael Whitlock. It is tempting to suppose that C. E. Whitlock was Michael's son. He announced his arrival in 1774 and towards the conclusion he says: "Those ladies and gentlemen who please to honour him with their commands (during the stay of the Comedians) are requested to favour him with them at Mrs. Gale's, Newgate Street." This reference to the theatre seemed to be interesting and I referred to the theatrical play-bills and to my pleasure I discovered that a member of the Company performing at the theatre in the Bigg Market was Mr. Whitlock. He never seemed to take a prominent part but this might well have been due to the fact that his dental practice occupied much of his time. During the first season he was given a benefit and the play that he selected was "As You Like It".

Mr. Whitlock appeared with the Company every year and in 1781 he managed the players. The Company had their ups and downs, including a burglary as the result of which they lost 80 volumes of plays. In 1785 it was announced that the Company would only be there for a short time, until April and it is rather surprising to find in the *Newcastle Chronicle* of April 30 the following announcement: "Mr. Whitlock, dentist, presents his respectful compliments to the ladies and gentlemen of Newcastle and begs leave to inform them that being under an indispensable necessity of quitting this place without a possibility of completing the various orders they have been pleased to honour him with, he intends to return about the middle of the second week in May in order to finish the business he is now obliged to leave undone as likewise to execute any such commands he may be favoured with in the interim. Those ladies and gentlemen whose orders he has received and which form a multitude of business he has not been able to comply with will be first attended to, others in the regular course. Mr. Whitlock embraces with deepest sense of gratitude this opportunity of returning his most unfeigned thanks to his friends and the public for the many favours confirmed upon him and assures them that nothing shall be wanting on his part to meet their future commands and approbation."

This seemed to indicate a rather hurried departure, the notice is dated April 15 and appears in the issue of the 30th. 1785 was an important year for him for he married Miss Elizabeth Kemble at York. She, too, was an actress and sister of the famous Mrs. Siddons and Mr. Stephen Kemble. Could this sudden departure have something to do with his marriage at York? Mr. Whitlock's wife joined the Company, acted in Newcastle and her first appearance was in February 1786. With Mr. Austin, Whitlock took over the management of the new Theatre Royal opened in 1788, a great occasion on which the bells of St. Nicholas' and St. John's were rung. He gave up the management of the theatre and about 1797 set out for a ten-year visit to America where it is stated he acted with success. He returned and in the Directory of 1811 is found to be one of the three dentists then in practice in Newcastle.

Newcastle has been extremely fortunate in the calibre of her medical historians and very little seems to have escaped Dr. Embleton, Professor G. H. Hume and Sir William Hume, Dr. Garnison, the late Professor Grey Turner and Professor F. C. Pybus. However, two small advertisements seem to have slipped past their notice with regard to the first resident surgeon and dentist in Newcastle, Frederick Horn. He was a surgeon in the Navy and

through the help of Admiral Osborne we now know that he served on the following ships:

Lynx from May 1, 1777 to May 6, 1778
Medway „ May 15, 1778 to June 4, 1780
Grafton „ June 6, 1780 to September 10, 1781
Crown „ March 17, 1782 to December 10, 1782

Dr. Embleton gave us the main information about him. He was appointed surgeon to the Royal Infirmary in 1800, took part in a celebrated discussion with Dr. Clark and Dr. Fenwick with regard to the fever wards, was a surgeon to the Dispensary and took an active part in the local Medical Society, of which he was the Vice-President for seven years and President in 1796. He contributed a number of papers to the Society and died in 1808 and was succeeded by his son in the appointment as surgeon to the Infirmary. In the Newcastle Directory for 1790 he is listed among the surgeons but in that of 1801 he describes himself as a surgeon and dentist. I was pleased to discover that he made the following announcement in December 1782:

"Frederick Horn takes this opportunity respectfully to acquaint the friends of his late uncle Mr. Henry Gibson that from some unavoidable circumstances (the ship of which he was surgeon being ordered to Gibralter and etc.,) he was prevented from addressing them sooner and soliciting the honour of their future favours in his professional capacity. As Mrs. Gibson is connected with him in the business he respectfully solicits the favours of her friends and flatters himself that his having attended the most eminent professors in London in the surgical and medical line and having been near six years a surgeon in H.M. Navy will have some weight in inducing those whom he has the honour to address and to give credit to his qualifications and assures them that his utmost abilities and attention shall be exerted to give satisfaction." In this interesting statement there is no mention of skill in dentistry and I wondered what type of a dentist he was. Imagine my delight when turning over the pages of the *Newcastle Courant* I found in the issue of July 29, 1786, the following:

"Frederick Horn, surgeon, acquaints the ladies and gentlemen of Newcastle and its neighbourhood that he has just returned from London where he has been completely instructed by an eminent practitioner in the business of a DENTIST. He scales and cleans and performs all the operations on the teeth, makes and fixes artificial and removes or prevents the irregularities which take place in the teeth of young people at the time of getting their second set."

The reference to the scope of Horn's work is of considerable interest to those of us who are dentists and of particular interest is the reference to children's teeth, as orthodontics is one of the most important branches of dental surgery to-day.

We find that a number of travelling dentists visited Newcastle. In 1761 Mr. Nathaniel Lee, an operator for the teeth, claims that he was present in Newcastle by the King's Authority.

"The famous Mrs. Bernard from Berlin and Brandenberg" who possessed "an infallible secret for cleansing the teeth and rendering them as white as alabaster notwithstanding they may be as black as coal remarkably done without use of an instrument." She was to be enquired of at the Half Moon entry in the Bigg Market. This was in 1773.

Mr. Marks, Jacob Hemet and Hemet Hart from Mannheim also stayed in Newcastle for a short while at different periods. I wonder if Jacob Hemet was a relation of George II's dentists—Peter Hemet senior, and Peter Hemet junior. In 1783 Mr. Crawcour, surgeon dentist, stayed for a short period and practised in Newgate Street. It is of considerable interest to us as this name is well known in dentistry because of the brothers Crawcour who early in the nineteenth century emigrated to America and started the row which is usually known as the Amalgam War. Was this man a relative—perhaps their father?

Messieur Le Sec, who was a pupil of Messieur Burdet, dentist to the Queen of France paid the first of a series of visits to Newcastle in 1790. Burdet was a famous dentist and it seems possible that Le Sec was a refugee from the Revolution.

There is a picture which shows Ruspini operating and through the window can be seen the lantern tower of St. Nicholas' Cathedral. There is no evidence that he visited Newcastle professionally but he married Elizabeth Ord, the daughter of one of the county families of Northumberland. The eighteenth century was remarkable for the travelling doctors, a number of these were eye specialists. One of the earliest of these travelling doctors to arrive in Newcastle was "Dr. Rayne, a Low German physician, who for the public good gives notice that he dexterously cures all sorts of deafness in young or old, whether it proceed from cold, relaxation of the drum, continual noise or imposthume in the ear or any other

obstruction in the auditory nerves to the advantage of a great number whom he has cured and restored to perfect hearing, several having been deaf for above 30 years who now hear as well as any person living. He performs the cure without any manner of pain and with such a safe operation as was never before performed".

In 1751, in January, "Mr. Turner, French surgeon and man-midwife who has studied at Paris all branches of surgery and has upwards of twelve years' practice in hospitals abroad, as appears by the testimonials granted him by Messieur Martinière, first surgeon to the King of France and lived some time in London and other parts of England where he practised the art of surgery with great success, takes the liberty now to acquaint the public that he treats the most inveterate wounds, ulcers and other sores of all kinds if they are not hereditary . . . he never undertakes a cure without taking, if it is required, a consultation with the established physicians and surgeons of the place, or from another place and is ready to perform before them all such chirurgical operations. He gives his advice and operates on the poor gratis. Inquire at Mr. Shackleton's in Pilgrim Street."

In 1758 there was the visit of Dr. Stalk, "occulist to the Royal Highness the Prince of Wales who lately restored several hundred to sight in Yorkshire such as have lost their sight or affected with any other disorder of the eye should apply to him at his lodgings."

Another ophthalmic specialist was Dr. Dove who came to Newcastle in the 1760s. Dr. Toscano, "the celebrated Danish physician", had an unfortunate quarrel with his interpreter when in Newcastle of which he gives full details in several public announcements.

The celebrated Dr. Graham visited Newcastle on several occasions and gave some of his usual spectacular performances, for instance in 1791 we find the announcement that "Dr. Graham and a young woman will give one more earth-bath exhibition this day Saturday July 9th, most positively for the last time from 12 noon to 6.0 o'clock in the evening in the large and commodious field at the side of Hanover Square, Newcastle in order emphatically to recommend this most natural, most safe and most radically efficacious practice to the world in general, especially to the country people". A week later he gave a similar demonstration in "Mr. Musgrove's garden to the left Without Westgate from 12 noon till 8 o'clock." "One woman who was scorbutic and one who suffered with leprosy and who baffled the physicians and surgeons in the Royal Infirmary in Edinburgh and in the Infirmary in Newcastle, and it is noted she stayed over fourteen months in each place without being cured, were publicly treated by the earth-bath method".

It is interesting that Mr. White, surgeon and man-midwife, No. 2 London House Yard North, the side of St. Paul's Churchyard, London, advertised in the Newcastle paper offering accommodation to pregnant ladies whose "situation requires a temporary retirement" and said that "they may be accommodated with apartments to lie in, agreeable to their circumstances and depend upon being treated with all attention and secrecy and their infants put out to nurse and humanely taken care of". The celebrated Chevalier Taylor was a frequent visitor to Newcastle where he gave himself great publicity.

As in most towns Newcastle had an open market place where stages were erected and upon which quack doctors were able to hold the attention of the crowd. There is a record of such a practitioner. "Dr Gibbons from London who keeps the public stages in Newcastle upon Tyne cures all sorts of agues, without giving the Jesuit's bark, in the space of 24 hours—no cure, no money. . . . He is the only noted man in the nation for this distemper and by reason the doctor's stay will be short. He advises all who have a mind to be cured to come before it is too late. He is to be spoken with at Mr. Rainton's in St. Nicholas Church Yard Newcastle." In a subsequent notice it says "he is to be spoke with at his chambers every market day near his stage".

I was amused to read in the *Courant* in 1761 "Wanted immediately a brisk active man to serve a travelling doctor as an Andrew. He must be a person of drollery and ready wit, if he has followed that calling before he will be the more acceptable, or if he plays an instrument. Like wise wanted a second-hand trumpet, cheap. Inquire of the printer of this paper. No letters answered unless post is paid."

The content of this paper lays me open to the charge of being a most biased type of historian. I have made no reference to Physicians such as Adam Askew, John Rotherham, John Hall, John Fenwick, John Clark—to mention only a few of the leading medical men who have not been included. How can I justify their omission? I have referred to Newcastle's fortune in the quality of her medical historians and as the physicians were men of distinction in the town practically all have been mentioned in some detail in the previous published works.

I am most grateful to Mr. Austin Hinton, Librarian to the Central Library, Newcastle, and to his assistants in the Reference Room, particularly Mr. Grimshaw and Mr. Muir.

Whither Medical History? [*Abstract*]

PRESIDENT'S ADDRESS

By DOUGLAS GUTHRIE, M.D., F.R.C.S.Ed., F.R.S.Ed.

DR. DOUGLAS GUTHRIE suggested that the time had come when the question "Whither Medical History?" might be asked with profit, even though it was impossible to supply an immediate answer.

It was interesting for the History of Medicine Section to look back to the date of its birth, when its founder, Sir William Osler, wrote to a friend in November 1912: "We have made an excellent start with our new Historical Section at the Royal Society of Medicine. There were over two hundred at the first meeting, so I hope it may be a success."

To-day, nearly half a century later, they might well pause to take stock of the situation. In this age of specialism, the art of medicine was in danger of being neglected, and this Section of a great Society, the only Section which was in no sense a specialty, and which still used a vocabulary intelligible to all, could play an important part in helping to counteract the somewhat narrowing effect of the present-day trend in medicine.

History provided an essential basis to medical education, and perhaps never before had there been so great a need for quiet retrospection, in order to look forward with clearer vision.

Moreover, there was a constant demand for fresh interpretations of historical facts to meet the varying outlook of each new generation of students.

Science had profited greatly from the specialist trend, but it could not supply all the answers to medical problems. There was still a subtle "something" which defied analysis, and it was not improbable that a closer study of the primitive attitude towards health and disease, the supernatural approach, might bring us nearer to the solution of problems which science alone could not solve.

There was also a need for a more philosophical approach to medicine, so that thought and reason might keep pace with observation and experiment. The time had come, too, for a re-statement of the Hippocratic oath in terms suited to modern conditions. Unfortunately this ancient and influential charter of medical conduct was almost wholly neglected in English medical schools, although in all four Scottish universities it formed an important item in the ceremony of medical graduation.

Dr. Guthrie also discussed the need for more widespread teaching of the history of medicine. A short course of 6 or 8 lectures, giving an outline of the main trends of medical thought, and an account of the leading pioneers, sufficed to interest the student, who might then continue to explore this exciting field for himself. Some account of the history of the particular medical school ought to be included, and due tribute should be paid to the importance of medical ethics. The history of each of the various branches of medicine was best included within the subject rather than in any separate lectures. One historical lecture might suffice, and it ought not to be an introductory lecture, being best deferred until the student already knew at least part of the subject, and could therefore appreciate an account of its history. Lectures were not the only means of approach to history. Exhibits of books, manuscripts, photographs, instruments and apparatus should be available, clearly and amply labelled. Societies devoted to medical history should include among their members librarians, chemists, nurses, dental surgeons, and indeed all who might be interested. There ought also to be a close link with general historians, of whose studies medical history is simply one aspect.

The wide appeal of medical history was one of its main attractions, in this age of centrifugal specialism. It was a valuable means of bringing together again all the various specialists, and was, perhaps, the best method of retaining the interest of the entire profession in that attitude towards medicine which, since the days of Hippocrates, has been so aptly termed "The Art".

Section of Surgery

President—Eric A. Crook, M.A., M.Ch., F.R.C.S.

[*January* 2, 1957]

Non-specific Conditions of the Large Intestine

PRESIDENT'S ADDRESS [*Abridged*]

By Eric A. Crook, M.A., M.Ch., F.R.C.S.

It is my intention in this Address to consider certain problems that are not yet fully solved in connexion with diseases affecting the lower reaches of the alimentary tract. Two problems in particular have provided interest in recent months—that of the ætiology of ulcerative colitis and that of the pathological processes that take place in lymphogranuloma venereum as it affects the rectum and the lower colon.

Lack of knowledge of the cause of a disease must, of necessity, place its treatment on an empirical basis. Certain diseases of the colon are in this category and the treatment has to depend on general measures to deal with the processes that are taking place, or, alternatively, on removal of part or the whole of the organ, leaving the patient at a physiological disadvantage. Idiopathic or ulcerative colitis is one of these conditions.

This name was first given by Wilkes and Moxon in 1875 after a study of colons from patients who had suffered from long-standing or recurrent diarrhœa. Many diseases were included that have subsequently been shown to have a separate cause and so have become separate entities, such as dysentery, typhoid and tuberculous ulceration, and, more recently, Crohn's disease and lymphogranuloma.

The ulcerative colitis that is now left after these separations is considered to be a disease entity, though the difference in the types of clinical picture presented suggests that it may, even now, comprise several different diseases. The common form starts in the left side of the colon and tends to extend both proximally and distally. A right-sided form occurs occasionally, being only one-tenth as common as that on the left. This is considered by Brian Brooke to be a different disease, in view of its tendency to involve the lower ileum and because of its liability to recur at a higher level if it is treated by ileostomy. Brooke further considers that a form of granular proctitis, that is occasionally observed and has little or no tendency to spread to the colon above, is also a different disease.

Crohn's disease and lymphogranuloma, though now usually considered separate and distinct from ulcerative colitis, have many points of similarity. Crohn, in 1932 in his original description of ileitis, showed the pathology to be different in the disease he described from that found in "right-sided ulcerative colitis". He described the clinical picture and the tissue changes that take place.

George Lumb in 1951 gave an account of the pathological changes that are found in Crohn's disease and ulcerative colitis and considered there was great similarity between the two. He stated "we appear to be dealing with a non-specific inflammatory lesion, indistinguishable from other inflammatory lesions", the changes being (i) thickening of the bowel-wall, (ii) narrowing of the lumen, (iii) lumpy mucosa (cobblestone appearance when the ileum is involved, pseudo-polyposis when the colon is affected), (iv) infection around the bowel.

Brooke (1954) in his treatise on ulcerative colitis considers the pathological changes in the colon, when ulceration occurs in association with Crohn's ileitis, to be different from those found in ulcerative colitis. Bensaude and Lambling of Paris showed in 1936 that certain inflammatory diseases of the rectum were due to the virus of lymphogranuloma venereum. The uncertain state of our knowledge of the ætiology of Crohn's disease and of ulcerative

colitis and the doubts about the mode of involvement of the rectum by the virus of lymphogranuloma have suggested the comparison that I propose to make between these three conditions.

This comparison is made from five aspects: (i) the incidence of the condition; (ii) the course it takes; (iii) the pathological changes found in the disease; (iv) the possible causes; and (v) the response to treatment.

(i) *Incidence*

In Crohn's disease we find the majority of cases occur between the ages of 20 and 30 and especially at the earlier part of this period. There is a slight preponderance of males over females and there are instances reported where more than one member of a family has been affected. Crohn quotes many instances of this in his early series. All classes of society are affected equally in ileitis and race and climate have no influence. The temperament may be highly-strung and anxious in some cases but the personality of the patient suffering from Crohn's disease is more stable than is the case in ulcerative colitis.

In ulcerative colitis the main incidence is between 20 and 40 years of age. There is a definite preponderance of females. In a recent review of cases made by Ian Macdougall at the Gordon Hospital this is 1·5 female to 1 male. Sedentary workers are more frequently affected than those who do manual work. The condition is more common in those of higher educational standard. In certain communities that are composed mainly of the poorer classes the condition is rare. At the City Hospital, Boston, U.S.A., a hospital of some 2,000 beds and serving the poorer part of the city, I found that ulcerative colitis was considered to be a rare disease. It is interesting to note that in Jamaica the disease is almost unheard of, the occasional case that does occur being usually in the white population of the island which constitutes less than 5%. Sufferers, for the most part, have rather unusual or abnormal personalities. They are inclined to be weak and dependent on others. Many of them are over-conscientious and sensitive, having a shy and timid disposition. They have a highly-strung and tense temperament. The onset of the disease or of its exacerbations is often precipitated by a superimposed emotional disturbance.

In lymphogranuloma affecting the rectum and colon, the incidence is limited almost entirely to the female. This is probably explained by anatomical factors, to be discussed later. The disease does not occur in the British Isles except for the occasional case in the larger ports and it is found mainly in the negro races. It is very common in Jamaica in the form limited to the genital tract and also that involving the rectum. In the U.S.A., series of cases are reported and it is found to occur twice as commonly in negro as in white people. The disease is reported in France but is relatively rare.

In comparing the incidence of the three diseases we find differences of susceptibility in each. In Crohn's disease there is some hereditary predisposition, in that several members of a family may be found to suffer. In ulcerative colitis personality and temperament show some peculiarity in most cases. In lymphogranuloma, racial differences determine the liability of occurrence. There is therefore a different background in each of the three diseases.

(ii) *The Course*

In considering the course that the three diseases follow we recognize that Crohn's disease may be found in an acute or a chronic form. The acute form presents a clinical picture similar to that of appendicitis, but differing in having associated diarrhœa. Some of these cases, rather less than half, settle down and finally resolve completely. The others fail to clear up and pass on to the chronic form of the disease. The onset of Crohn's disease is in most cases gradual, and the significance of the early symptoms of periodic attacks of diarrhœa and general weakness is not appreciated by the patient. The diarrhœa is not so profound as in ulcerative colitis. The early symptoms are often present for two or three years before they are recognized as being due to Crohn's disease. The infective lesions in the rectum and surrounding tissues may appear at this early stage and call attention to the significance of the diarrhœa. They are a special feature of Crohn's disease and not simply caused by the diarrhœa. They start as a surface infection, often in a crypt of Morgagni and from this infection escapes through the bowel wall and causes a perirectal abscess, which in its turn gives rise to a fistula. The stool is watery, and contains no visible mucus or blood. A series of cases that I reported in a paper read to the Royal Society of Medicine in 1935 showed, however, that anæmia due to blood loss may be an early feature of the disease. Abscess formation near the infected ileum and subsequent fistulæ are frequently found, the latter opening on the abdominal wall—especially if there has been a previous appendectomy—or into another portion of the bowel or the bladder. Symptoms of intestinal obstruction are liable to develop at a later date. Crohn's disease is usually progressive in

its course, advancing rapidly in some cases, slowly in others and sometimes remaining localized in the terminal ileum for many years.

The course taken by ulcerative colitis is rather more varied. The onset is usually more acute and is followed by periodic attacks of varying severity and length. In some cases the first attacks are mild, becoming later more severe and more frequent, until the symptoms become continuous with periodic exacerbations, the essential features of the attack being abdominal pain and diarrhœa in which blood and mucus are passed. Anæmia is a constant finding, but abscesses and fistulæ do not occur except in the perianal region. The disease has a long course. Intestinal obstruction seldom develops.

In lymphogranuloma a spurious diarrhœa is found in the early stages. Blood and mucus are passed and the fæcal material is solid. Abscesses and fistulæ often occur. Obstruction due to stricture formation is a constant feature.

In the course followed by the three diseases the early stages are marked by the presence of diarrhœa, attributable to irritation of the surface layers of the bowel, the character of the diarrhœa varying with the region involved. In Crohn's disease and ulcerative colitis the onset may be acute, passing into the clinical form in which the disease is most often observed. Recurrent attacks with intervals of freedom may continue for years but eventually the symptoms become continuous, presenting periodic exacerbations. Ulcerative colitis in its behaviour tends to be more capricious than Crohn's disease, some attacks being more violent than others, and in some cases unexpected rapid improvement takes place. In general, both diseases are relentless in their course, very few cases clear up under treatment; in some, advance is prevented, but in the majority operative treatment, removing the affected bowel, is necessary.

In lymphogranuloma the earlier course of the disease has not been so fully studied. The rectal manifestations are an extension of the primary disease in the genital tract with the possible exception of the occasional case which occurs in the male. The course, however, is similar to that of the other two. Recurrent attacks occur over a period of many years and obstructive symptoms are gradually added to the picture.

(iii) *The Pathological Changes*

In comparing the pathological changes, we find in Crohn's disease an inflammation of the mucosa and submucosa—with or without ulceration—swelling and proliferation of lymphatic endothelium in both the intestine and the lymph glands—with occlusion of lymphatics and resultant œdema. The changes cause a generalized thickening of all coats of the bowel with a boggy mesentery and enlarged lymphatic glands. The bowel becomes a solid tube and a fibrinous exudate forms on its serous surface. Adjacent coils become adherent and a tangle of bowel, matted together, is formed round the coil that is primarily involved. These adhesions are followed by escape of infected material and abscesses form between the coils with subsequent internal fistulæ. Advancing changes also take place in the mucosa of the bowel. In patches denuded by the ulceration the mucous membrane is replaced by scar tissue covered in part by a modified columnar epithelium. Islands of mucosa that are left become œdematous and present a "cobblestone" appearance. These changes may be limited to one region which is most frequently the terminal ileum but "skip lesions" are found at a distance above or below with intervening healthy "skipped areas". Hadfield (1939) describes the histological appearances as those of submucosal-coat thickening with lymphatic tissue showing well-defined non-caseating giant-cell systems, free from acid-fast organisms. Similar changes are found in the regional lymphatic glands. There is associated obstructive lymphœdema. This, in the course of time, is replaced by fibrous tissue which tends to contract and to result in stricture formation. In ulcerative colitis the earliest changes are found in the mucosa which becomes swollen and red with a tendency to bleed when touched by the examining sigmoidoscope. In some cases no ulceration is visible, in others multiple shallow ulcers may be seen. These changes can usually be recognized but proof of the condition and an indication of further disease in the colon above can be obtained by biopsy of the rectal mucosa. It has been the practice at the Gordon Hospital to study these cases by taking a fragment of tissue for section at 11 cm. from the anal orifice. There is no special reason for selecting this level for the biopsy other than the advantage of having a fixed point in the bowel so that comparisons can be made more accurately. George Lumb has shown that characteristic changes of ulcerative colitis are shown by the special inflammatory process and the alteration in the architecture of the mucous membrane. The ulcers in the colon extend and the mucosa becomes undermined and partially destroyed. Remnants of surviving mucosa stand out as tags and, becoming œdematous, have the appearance of polypi—a state of pseudopolyposis. This stage may be reached before any change is visible in the external appearance of the bowel as seen at laparotomy. The process gradually penetrates more deeply through the muscle wall producing a state of thickening and of hyperæmia of the serous coat. There is no tendency for adhesions to neighbouring

coils of bowel to take place and fistula formation does not occur. The enlargement of para-colic lymph glands is only slight. Areas in the bowel lumen that have been denuded of mucosa become covered with a typical epithelium and scarring takes place in their base. A rigid narrow state of the bowel may result but true stricture formation is unusual though it sometimes takes place at the recto-sigmoid junction. The histological changes described are submucosal œdema, mucosal hyperplasia, necrosis and ulceration, associated with diffuse round-cell infiltration including eosinophils and, in the later stages, advancing fibrosis. The picture is one of a pathological state rather than a specific process.

In lymphogranuloma when it affects the rectum, the earliest changes are seen in the mucous and submucous tissues. These changes may be limited to the lower part of the rectum but in many cases they extend to the upper rectum and the pelvic colon. Cases are reported where the disease has been found as high up as the cæcum. These lesions, when they occur in the colon, are separated from the main disease by stretches of healthy bowel. In the barium enema X-ray, a saw-tooth pattern, indicating spasm, is shown in the early stages similar to that seen in ulcerative colitis. A granular proctitis is present with a swollen and congested mucosa and superficial ulceration with a blood-stained muco-purulent discharge. Lymphatic œdema is found in the outer layers of the rectal wall and perirectal cellular tissue, causing an appearance of elephantiasis and tag formation round the anal orifice. Suppuration in the cellular tissues occurs and, after the bursting of the abscesses, fistulæ are found with openings in the perianal skin. In the female a recto-vaginal fistula may be found. Narrowing of the rectum is produced by œdema in the wall and later by fibrous tissue which results in a tubular stricture 3 in. or more in length. The X-ray appearance is then very similar to that of the "string" sign seen in Crohn's disease. No appreciable enlargement of the regional lymph glands is found at laparotomy at this stage—a feature that is characteristic of the genital manifestations of the disease. The histological appearances of the tissues are described as those of an intense non-specific granulomatous inflammatory process. The cellular tissue is infiltrated with leucocytes and plasma cells and in places there are collections of endothelial and giant cells surrounded by lymphocytes and numerous plasma cells. Lymphatics are dilated and contain lymphocytes and plasma cells and an increasing amount of fibrous tissue is found. In two cases of lymphogranuloma reported by Hawe (1951) the following changes were found: "Non-specific inflammatory reaction. Cellular infiltration of plasma cells, monocytes and polymorphs, with accompanying fibroblastic reaction, some foci of epithelioid cells resembling tuberculous systems but without caseation. Changes extend through all coats of the gut with maximum intensity in the submucous layer."

So in the pathological changes we find great similarity in the three diseases. Lumb (1951) considers the resemblance between Crohn's disease and ulcerative colitis to be so close that they may be the same disease. In the later stages of the pathological processes, however, definite differences do appear but the tissue changes of Crohn's disease and those of lymphogranuloma come to resemble each other more closely. It would seem that the pathological evidence puts Crohn's disease and lymphogranuloma together and that ulcerative colitis cannot be linked directly with either.

(iv) *The Possible Causes*

In considering the possibility of a common cause for the three conditions we find that in Crohn's disease the ætiology has not yet been fully explained. Search has been made for a specific organism but none has been found. At the Mayo Clinic in 1938 a series of cultures was taken from specimens and lymph glands in the operating theatre and many organisms were grown but the findings were not constant. Dysentery organisms were not found. The presence in the microscopic section of giant cells that are proved not to be tuberculous in origin has suggested that certain small irritating food particles, acting as "foreign bodies" may be a causative factor. A virus has been suggested as a cause in view of the similarity between the tissue changes in Crohn's disease and lymphogranuloma in which latter the association with a virus has been established. If the ætiology were the same, however it would seem probable that the two conditions would occur together at times. This has not been recorded; Frei's test has proved to be negative in ileitis. However, some other virus may be responsible. The behaviour of ileitis in its tendency to spread and its liability to recur after resection does seem to point to some infective cause and we have ruled out bacteria as a possibility. It has been suggested by Chess and others in 1950 that some mechanical irritation of the mucosa of the ileum may be the cause. In experimental work on dogs, the giving of sand by mouth has produced ileitis, but in human beings no association has been found between the ingestion of irritants and the development of ileitis. Trauma, with interference of the blood supply of the ileum and resulting pathological changes in the tissues, has been suggested but there is no support for this theory. The frequent sequel of appendicectomy and ileitis has suggested an association between the two. A recent operation at

which the appendix was difficult to find and even more difficult to remove was followed by recognizable Crohn's disease a few months later. The trauma involved at the operation may have been a factor in causing the latter, but it seems more likely that ileitis was present at the time of the operation but had not reached a recognizable stage. We recognize the close similarity between the clinical pictures of acute appendicitis and the acute form of Crohn's disease. Enlargement of the regional lymph glands is a constant feature of terminal ileitis and it has been suggested that lymphatic block may constitute the initial process which leads to lymphatic œdema in the mesentery and wall of the terminal ileum with subsequent inflammatory changes. Experimental blocking of lymphatics in animals has resulted in thickening of the bowel wall. This does not, however, prove that the changes proceed in this direction in the human body.

The ætiology of ulcerative colitis is also a mystery. In its acute stage the disease is indistinguishable from bacillary dysentery, both clinically and pathologically, and is only dissociated by bacterial evidence of the latter. It is, however, possible that an attack of bacillary dystentery may be the onset of ulcerative colitis and that the tissue changes of the latter are kept alive by organisms that normally inhabit the bowel after the dysentery bacilli have disappeared. The association of a diplostreptococcus described by Bargen in 1924 has not been confirmed by later workers and the theory has been abandoned. Vitamin deficiency has been blamed but is not present until the later stages of the disease when it is more likely to be the result rather than the cause and is attributable to the reduced diet and the rapid passage of food through the bowel. In 1933 Florey wrote on "the function of mucus and the early stages of bacterial invasion of the intestinal mucosa", and in 1949 Meyer and others described an enzyme "lysozyme" that had power to destroy mucus and was present in high concentrations in the bowel content in ulcerative colitis. He suggested that the enzyme destroyed the mucus and so removed the natural protection of the cells of the bowel, exposing them to digestion by normal proteolytic enzymes and to infection by normal bowel organisms. This mucolytic enzyme is not present in normal stools. Its high concentration in ulcerative colitis has been considered by Sammons (1951) to be the result of lysis of the pus cells that are present, being therefore the result of the secondary infection of the bowel wall and not the cause. The possibility of an allergy has been considered. Sigmoidoscopy carried out as a routine in minor bowel disturbances shows at times a patchy condition of the mucosa with raised vascular areas and small papules—a state suggestive of urticaria of the skin. This theory seems unlikely, as sufferers from ulcerative colitis are not as a rule subject to allergic conditions. The emotional instability that is often associated with the onset of ulcerative colitis and the known effect of the emotions on alimentary function have suggested a search for a neurological cause of the disease. Wright *et al.* in 1938 described the effect of stimulating the sacral division of the parasympathetic nerves, the nervi erigentes, in cats, thereby producing increased muscular activity and secretion of mucus. In dogs, long-continued stimulation by various methods including cholinergic drugs, has been shown to lead to colonic engorgement, hæmorrhage and ulceration, which may prepare the way for further injury and secondary infection. Can we consider the local reaction of the colon in ulcerative colitis to be the result of long-continued overstimulation of the parasympathetic nerves, particularly the sacral outflow which supplies the distal colon and rectum?

The ætiology of lymphogranuloma is on a firmer footing. Bensaude and Lambling (1936) described their investigations of proctitis, especially when associated with stricture formation. They had found that lymphogranuloma was a frequent cause, the specific intradermal test that had been introduced by Frei in 1925 being positive and also the complement-fixation test. This established a recognized rectal lesion as a granulomatous state produced by a known virus. The virus of lymphogranuloma had been isolated by Hellerström in 1930. Bensaude and Lambling expressed the view that the virus reached the rectum from the genital tract via pelvic and perirectal lymphatics, claiming that the disease affected the outer layers of the rectal wall before it reached the mucosa. Hawe (1951) considered that in the female the infection reached the rectum from the vagina by the perirectal lymphatics, whereas in the male the rectum was involved by direct inoculation of the anal mucosa. Roger Miles has recently carried out a large-scale investigation of lymphogranuloma in University College of the West Indies, Jamaica and has shown that in a large proportion, possibly all, of the cases of rectal involvement the infection has started on the mucosal surface of the bowel. He considers that in the female, the rectum is infected by spill from the vagina. In the male, in whom the rectal manifestations of lymphogranuloma are much less frequent, the rectum is probably involved primarily by direct implantation of the infection on the mucosa. The cause of Crohn's disease and of ulcerative colitis is still undiscovered but that of lymphogranuloma is known. The similarity of tissue changes in Crohn's disease and lymphogranuloma suggests that the former may be due to a virus infection though not the specific virus established as the cause of lymphogranuloma.

(v) *Response to Treatment*

In considering the response to treatment it is found that Crohn's disease and ulcerative colitis behave in much the same way. Fundamental principles in treatment form the mainstay—rest and a diet high in protein, vitamins and calories and low in residue with plenty of fluid. The insoluble sulphonamides sulphasuxidine and sulfathalidine have a place in controlling secondary infection. Of the antibiotics, chloramphenicol and aureomycin are used, the latter having a wider range of action and usually giving some improvement and, occasionally, a complete remission. They have, however, no curative effect on the established disease.

In lymphogranuloma venereum, Roger Miles describes a series of cases treated, some with chloromycetin, some with erythromycin and others with aureomycin and with each drug, rapid improvement was obtained. Pain and tenesmus disappeared, blood and mucus cleared up and the sigmoidoscope showed definite improvement in the state of the mucosa. These cases were followed up and in over 70% of patients treated, great improvement or complete cure was obtained.

As surgical measures are often necessary, their effects should be considered. In Crohn's disease a by-pass for the intestinal contents by ileo-transverse colostomy has been abandoned in favour of a resection of the affected bowel. Resting the diseased area led to healing in some, but not all, cases. In ulcerative colitis the establishment of an ileostomy gives immediate benefit but subsequent removal of the colon is necessary to obtain a cure. In cases where the rectum is appreciably involved this organ must be removed as well. The need for this has been shown by Brooke in a case where arthritic symptoms were associated with the original disease, removal of the colon as far as the rectum did not cure the joints but this cure was obtained by a subsequent removal of the affected rectal stump. In cases where the rectum is not extensively involved, Aylett (1956) at the Gordon Hospital has shown that ileorectal anastomosis after excision of the colon gives good results and no trouble from the retained rectum follows. In lymphogranuloma venereum it has been stated above that antibiotics give good results in the earlier stages when the disease is limited to the mucous and submucous coats of the rectum. This treatment can be combined with gentle dilatation of the bowel in the early stages of narrowing, but surgical resection is necessary when a definite stricture has developed or infection has spread to the perianal tissues with abscess or fistula formation. The mere establishment of an iliac colostomy above the diseased area without resection of the latter is useless.

All three diseases responded to the insoluble chemotherapeutic drugs in variable degrees. The effect produced seems to be due to the action of these drugs on the secondary infection present; they have no curative effect. Surgical measures adopted to rest the diseased bowel by diverting the contents relieve but do not cure; excision of all the diseased tissue is necessary for this, otherwise there may be a recurrence. A "skip lesion" in Crohn's disease and in lymphogranuloma may have escaped notice or, in ulcerative colitis, the colon may have been involved beyond the point visible to the naked eye.

General Comparison

The similarity of the early stages of all 3 diseases suggests that they may be one and the same disease. The special features in each may be explained by the local differences in the region of the bowel involved, modified by idiosyncrasies of the patient and differences in race and climate. As the disease progresses, however, though Crohn's disease and lymphogranuloma maintain many parallel features ulcerative colitis becomes more like a separate disease: the underlying process does not behave like an infection as appears to be the case in Crohn's disease and lymphogranuloma. In the latter an infection has been shown to be the cause and it may well turn out to be the explanation of the former.

DISCUSSION ON DYSMENORRHŒA AND UNEXPLAINED PELVIC PAIN

Mr. Wilfrid Mills: *Dysmenorrhœa*

Dysmenorrhœa still presents a fascinating problem. Despite investigation of intra-uterine pressure with balloons (Moir, 1934) and uterine blood-flow with radioisotopes (Flick *et al.*, 1956) it remains largely unsolved. There is no final agreement on the pathway of sensory nerves from the uterus nor the reason for uterine pain being referred to so many different areas of the skin. We cannot even say how far the pain is caused by spasm of uterine muscle or by ischæmia from inadequate blood supply. It has been suggested that it may be associated with organic disease of the sympathetic ganglion cells (Davis, 1938), of the ovary (Browne, 1949) or even of the ureter (Read, 1951). There is often a suggestion of emotional immaturity about these patients and this is perhaps borne out by the finding of a tight hymen precluding pelvic examination far more often than in girls of an equivalent age group with menorrhagia.

The extent of this disorder is considerable and it seems to vary widely between social classes and nations. A figure of 16% has been quoted from among British nurses (Bishop, 1950). The number of cases seen by any gynæcologist will depend partly upon his reputation for sympathetic interest and his success in the past, but also upon the skill and self-reliance of the practitioners whom he serves. It is difficult to get any unselected series for most specialists see only the few resistant cases.

Attitudes towards treatment are most variable. Some gynæcologists prescribe only simple measures and consider the whole problem to be over-rated, regardless of nuisance to industry when young women are principally employed and require regular days off. Others observe that dysmenorrhœa is seldom seen among well-adjusted, sexually adequate and psycho-somatically sufficient women (Hamblen, 1945) and regard the problem as purely one for the psychiatrist. Perhaps they fail to appreciate the emotionally demoralizing effect of regular, severe and anticipated pelvic pain with its concomitant social disorganization. Others, more properly described as gynæcological surgeons, practise complicated ways of interrupting the alleged sensory sympathetic nerve pathways and persuade patients that a surgical operation is a small price to pay for the chance of a permanent cure. Those who understand the nature and action of steroid hormones feel that a solution should be well within their compass and in fact these hormones do give great relief to many patients. However, the family doctor probably cures or relieves far more of these sufferers than we realize by means of a multitude of relatively simple preparations. His knowledge of the upbringing and background of the patient together with her reaction to pain on previous occasions enables him to assess her far more competently than the gynæcologist meeting her for the first time.

I have done no research nor have I followed up a long series of cases treated identically in this condition. I have, however, recorded what my patients have told me and as this is a symptomatic condition the patient is surely the best judge of the results.

I shall deal only with that common type of dysmenorrhœa without demonstrable pelvic disease; it may start at puberty or some few years later but there should be no complaint of pain apart from the first few days of the menstrual loss. The patients are commonly unmarried and in their late 'teens or early twenties. Physical examination often shows unusual tightness of the ring of the hymen with sometimes hypoplasia of the vulva and vagina but there are generally no other abnormal findings.

Temporary relief or permanent cure may follow a great variety of therapeutic and other incidents and although the connexion may well be fortuitous it is tempting to believe in a causal relationship. I have listed some of these incidents and forms of treatment which, in my own experience, have been judged successful by the patient herself, after a reasonable interval of time (Table I).

It is also instructive to consider those occasions, fortunately less common, on which the patient is convinced that some incident or form of treatment has been responsible for significant deterioration in her condition (Table II).

It is easy to be sceptical as to the value of treatment in a condition where relapse is so common. But I have found a decided reluctance among these patients to express satisfaction unless relief has been obtained. The following cases illustrate some of these points.

TABLE I.—CONDITIONS CURING OR IMPROVING DYSMENORRHŒA

1. The passage of time
2. Marriage
3. Pregnancy (sometimes abortion)
4. Education and simple psychotherapy
5. Attention to bowel and physical exercise
6. Atropine and similar drugs
7. Peripheral antispasmodics (e.g. Priscol)
8. Œstrogen to inhibit ovulation
9. Œstrogen following ovulation
10. Androgens
11. Dilatation and other trauma to the cervix
12. Presacral pelvic neurectomy

TABLE II.—CONDITIONS AGGRAVATING DYSMENORRHŒA

1. Change of residence or occupation
2. Marriage, especially if infertile or unhappy
3. Abortion
4. Progesterone
5. Œstrogen inadequate to inhibit ovulation
6. Trachelorrhaphy

ILLUSTRATIVE CASES

I. Mrs. A. had already been treated elsewhere successively by D. and C., Gilliam suspension and then a second D. & C. but her dysmenorrhœa was still severe. Confidence was restored by inhibition of ovulation with œstrogen and the relief continued. Then a sequence of 3 abortions (2 being at 18 weeks) called attention to the incompetent cervix which was repaired by trachelorrhaphy. Her dysmenorrhœa immediately became intense and hysterectomy was demanded. Fortunately she was then cured by carrying a pregnancy to term.

II. Miss B., a trained nurse, had had little relief from analgesic drugs and was advised to inhibit ovulation with œstrogen. In the first month the dosage was inadequate, the period started during the course of treatment and the pain was more intense and prostrating than ever before, requiring morphine for relief. Subsequent correction of dosage was satisfactory and pain was fully relieved.

III. Mrs. C. was first seen aged 17. Her dysmenorrhœa was completely relieved by œstrogen from the seventeenth day until the onset of the period and the relief persisted after treatment had been discontinued. Subsequently she relapsed slightly but required no further treatment or advice until the pain returned, following an abortion soon after she was married.

IV. Mrs. D. had a bad family history of dysmenorrhœa and obtained no relief in her youth. She married and was advised to have a family but each of her two confinements brought trivial improvement that lasted only a few months. At 35 she welcomed hysterectomy as her monthly prostration interfered with her hunting appointments.

V. Mrs. E., an exceptionally gifted and intelligent woman, suffered a severe disorder of uterine action at her first confinement. On being questioned about dysmenorrhœa, she replied: "My dysmenorrhœa disappeared as soon as I heard a psychiatrist say that it was always emotional; it never returned."

Discussion.—The conclusion must surely be that there are many different causes for and different mechanism involved in the production of this common symptom, and that each patient requires individual assessment.

As a working hypothesis I try to fit my patients into one of six categories (Table III) and

TABLE III.—CLASSIFICATION OF PRIMARY DYSMENORRHŒA

1. Deficient uterine blood supply
2. Stenosis of cervix
3. Excessive luteinization
4. Pelvic congestion
5. Excessive innervation
6. Emotional factors

to treat them accordingly. Although the initial assessment may have to be modified later the classification works well in practice. Sometimes more than one factor may be operative. It is easy to imagine an avascular uterus which responds to marriage, pregnancy and œstrogen. The concept of a tight cervix is strengthened by the familiar experience that the difficult dilatation is subsequently the most successful. The idea of excessive progesterone producing a modified decidua has long been held to explain membranous dysmenorrhœa (Whitehouse, 1935) and to give a rational explanation for therapy with premenstrual œstrogen. The picture of uterine congestion is less easy to visualize but at least it would explain the success that may follow physical exercise, peripheral vasodilators and purgation in drawing blood away from the pelvic organs. The uterus that is too liberally endowed with sensory nerve endings is demonstrated in the patient who cannot endure a simple cauterization of the endocervix and who may require a sympathectomy operation; emotional and neurotic patients are familiar to us all.

In consultant practice some of these categories can often be excluded by the failure of treatment that has already been given, but there may be a secondary emotional imbalance due to frustration with the apparent incurability of the pain. The first prescription may in some cases be the inhibition of ovulation by œstrogen in order to restore the confidence of the patient in medical advice. This, if continued for several months, will sometimes produce so much permanent relief that further therapy is unnecessary, but otherwise there will now be ample co-operation from the patient in evaluation of other measures according to her probable classification. Patients with congestion have been cured, apparently permanently

by three or four months on testosterone; others have responded unexpectedly well to œstrogen given subsequent to ovulation. Dilatation of the cervix is used more freely in the married woman especially if infertile, but presacral neurectomy is very seldom employed by me as a formal procedure on its own.

Conclusion.—Since adopting the principle that primary dysmenorrhœa may be a symptom of several different uterine disorders, a classification has been evolved to satisfy the available evidence and to provide treatment on an individual basis. One of the results has been that these cases are now welcomed in the gynæcological department.

Mr. Wilfrid Mills: *Unexplained Pelvic Pain* [*Abstract*]

The problem of pelvic pain is one of diagnosis and ancillary methods were discussed. A personal series of 100 cases of pelvic pain shows a preponderance of young married women with family limitation. The final diagnosis will often depend upon the response to different forms of conservative treatment. Almost half of the patients have been considered as "functional" rather than "organic". Most cases obtain relief eventually if conservative forms of treatment are combined with attention to social factors. Radical surgery gives consistently good results.

Mr. Albert Davis: *Surgical Treatment*

In the absence of gross pathology the surgery for pelvic pain resolves itself into one or other of the several forms of sympathectomy. These range from simple stretching of nerve fibres to actual sympathectomy, and will be described seriatim in order of their severity.

Dilatation of the cervix.—This is, interestingly enough, the original sympathectomy, for it owes its results to rupture of the sympathetic plexus in the cervix itself. I described this plexus (Davis, A., 1933, *J. Obstet. Gynæc. Brit. Emp.*, **40**, 481) some twenty years ago and since then we have been able to trace its connexion with the main pelvic plexus of Lee Frankenhauser. It lies just beneath the epithelium surrounding the external os, and I have called it the "sub-epithelial plexus of the tip". It is the rupture of this plexus which is responsible for the relief of the pain in dysmenorrhœa, a logical explanation which disposes of our previous uneasy belief in the obstructive and angulation theories. To produce effective rupture of this plexus it is obviously necessary to tear the cervix. The nulliparous cervix ruptures as a rule after dilatation to No. 8 Hegar—it is a common finding to note how suddenly dilatation becomes easier at this stage, the larger dilators passing very easily afterwards. It is, of course, obvious that the laceration so produced should be controlled, and this is best accomplished by the use of graduated dilators (Fig. 1). The one illustrated is slightly

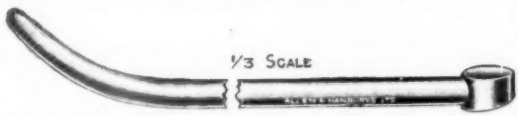

FIG. 1.—The author's graduated-stem uterine dilator.

graduated for about 3 in. from the tip, and each one passes through three sizes, 3–6, 4–7, &c. With this method approximately 30% of all cases of primary spasmodic dysmenorrhœa are cured, or adequately relieved.

Alcohol injection.—The rationale here is to destroy the uterine afferent nerves where they are most closely concentrated, i.e. in the pelvic plexus of Lee Frankenhauser. This lies at the side and in front of the ampulla of the rectum on either side, being formed by the fusion of the hypogastric plexus and the nervi erigentes from the middle three sacral nerves. The technique is to pass a needle into the plexus from the vagina. With the patient in the lithotomy position the cervix is seized with vulsella and retracted towards the left. The right fornix is further exposed with the aid of a flat lateral retractor. A long, graduated galserian needle is then passed horizontally through the vaginal mucosa at the side of the cervix for a distance of 0·5 cm., and the retractor removed. The needle is now passed backwards and outwards for approximately 1·5 cm., at an angle of 45 degrees to both the sagittal and coronal planes, and guided by a finger in the rectum to a point 0·5 cm. from the

side of the rectal ampulla. The needle is then withdrawn for 0·5 cm., and 1 c.c. of 95% alcohol injected, the needle point being kept slightly but continually moving. The same procedure is then repeated on the other side.

Bios and Young infiltrate the whole of the parametrium by injecting 8 c.c. of alcohol on each side of the cervix and body of the uterus. Their method owes its success to destruction of the most peripheral uterine branches of the pelvic plexus, and it seems more reasonable to alcoholize that structure directly in the manner just described, for the quantity of alcohol necessary is very considerably less. I have lately, however, combined the two methods by first injecting the plexus, and then placing 1 c.c. of alcohol in the parametrium close by the side of the uterus, so as to block any accessory nerve-fibres.

Perforation of the rectum with consequent cellular infection is avoided by making the injection 0·5 cm. away from that organ, as calculated from the internal finger. Injury to the ureter is prevented by adherence to the technique described, which keeps the needle point lateral to it. The uterine artery, if touched, usually slips away from the needle, but constant movement of the latter is a further safeguard.

Hofstatter has suggested that the injection of a destructive substance like alcohol into the loose pelvic cellular tissue might cause a local aseptic necrosis. I have not encountered this complication, and experience with alcohol injection elsewhere leads one to regard it as only a very remote possibility.

It is unnecessary to use more than 1 c.c. of alcohol on each side, for only a partial destruction of the plexus is aimed at. The upper part of the plexus contains the motor nerves to the bladder, which have been shown by Learmonth to be indispensable to the proper function of that organ. With the quantity of alcohol suggested these fibres escape injury, but it is conceivable that larger amounts might damage them, with consequent urinary disorder.

The results on the whole are relatively good, about 60% of cases of dysmenorrhœa being cured.

Presacral neurectomy.—The indications, technique and results were illustrated by a film.

Resection of utero-sacral ligaments.—This, one of the original sympathetic operations, has recently been revived with apparently good results. It is simple and effective in selected cases of pelvic neuralgia, but carries the risk of damage to the detrusor nerves of the bladder.

Ovarian sympathectomy.—This procedure advocated for the relief of pain of ovarian origin (ovulalgia), "Mittelschmerz", "ovarian dysmenorrhœa", &c., consists essentially in division of the nerve supply to the ovary; originally a tedious dissection of the nerve fibres in the infundibulo-pelvic ligament, it has recently been simplified to simple excision of 1 cm. of the whole ligament itself. Though widely advocated, the author's experience is that it is of little, if any, clinical value, and probably does actual harm by severing some of the control necessary for complete ovulation.

Intrathecal alcohol injection.—This is an occasionally valuable procedure for the relief of intractable visceral pain in recurrent carcinoma. It carries with it, however, the considerable risk of producing lower limb and bladder paralysis.

Mr. G. W. Theobald:

Pain may be regarded as an entity (and study along these lines is rewarding), as a guide to diagnosis, or as the most common symptom which clamours for relief. Pelvic pain is frequently associated with menstruation, but much of it is related to exercise and indirectly to the time of day, or may occur in association with micturition, defæcation, or coitus. On the other hand, iliac fossa pain may occur at very irregular and unpredictable intervals. It is important to bear in mind that constipation, colitis, and pathological changes in the renal tract may provoke unexplained pelvic pain.

In dysmenorrhœa the first period is rarely painful, and the pain may not start until months or years later. The onset of the pain may occur from half an hour to fourteen days before, and disappear with the flow, or it may commence with the flow and last either for a few hours, or until the period finishes. It may not commence until the second day or until the end of the period, and there are a few people who are never free from pain except when menstruating. In Bradford, dysmenorrhœa is hardly encountered in the mills and factories and is predominantly an affliction of typists.

Strain, study and hectic living may cause a woman to have a series of very painful periods although she normally suffers no discomfort. A famous swimmer stated that if she had to swim a race at the beginning of her period the flow stopped immediately and her next period was always painful. Conversely, women who invariably suffer from severe dysmenorrhœa nearly always have painless periods when they are brought into hospital for investigation.

Dysmenorrhœa has been cured by falling in love, by childbirth, by various operative procedures and by hormones, those used being progesterone, œstrogen and U.R.F. It is important to stress that œstrogen given during the last ten days of the cycle frequently suffices to prevent dysmenorrhœa. This disposes of the unfounded assumption that the onset of

primary dysmenorrhœa, in a girl whose periods were originally painless, is related to the commencement of ovular menstruation.

It may therefore be concluded that there is no direct correlation between dysmenorrhœa and either pelvic congestion or ovulation. Seeing that both primary and secondary dysmenorrhœa respond to similar therapy, I am not disposed to accentuate any difference in ætiology.

Dysmenorrhœa only accounts for a fraction of the pain which arises in the pelvis. The distribution of this pain is usually limited to the lower abdomen, and the inner and outer aspects of the upper portions of the thighs, and posteriorly to the lower sacral area. It may, however, simulate renal pain and even that associated with a gastric ulcer. Pain occurring along the outer border of the rectus abdominis muscle on either side, and at points where muscles are attached to the bony pelvis, or Poupart's ligament, may result from trauma and be strictly analogous to a tennis elbow. Similar traumatic pain may occur at many points on the back.

The most common type of pain is described as "nagging" like a toothache, while that associated with dysmenorrhœa may be "cramp-like". Patients occasionally describe the occurrence of sharp, breathtaking pain, which causes them to hold on to any available support. This sharp pain soon passes off, often completely, but may persist for several hours as a dull, nagging pain.

In the abdominal examination the distinction between pain and tenderness is important. Pain in the lower abdomen, and lower sacral region, unassociated with any area of tenderness, is clearly referred from some viscus. Tenderness which disappears when the abdominal musculature is tensed, is also referred, but the pain which persists in spite of taut musculature may arise wholly in the abdominal wall, or may contain a component of referred visceral pain.

On vaginal examination, movement of the cervix should cause neither pain nor discomfort. On the other hand it may provoke severe pain. The cervix can be moved in six different directions, and the different movements may provoke pain in four or five different sites. Such observations may often be made in a patient whose cervix appears to be healthy and in whose pelvis no abnormality can be detected. It may be observed, in parenthesis, that one of the main distinctions between primary and secondary dysmenorrhœa is that movement of the cervix in the former type is invariably painless, whereas in the latter it always provokes pain. It is apparent that the pain provoked by moving the cervix must arise in the parametric tissue, for it would otherwise be impossible to account for the fact that different movements provoke pain in different sites. Pain so provoked is frequently, but by no means invariably, the pain of which the patient complains. This is particularly true of dyspareunia caused by deep penile penetration.

On bimanual examination, the ovary is often found to be exquisitely tender. From time to time, however, it proves possible to move it into a position where quite strong pressure on it causes no discomfort. Further, when the abdomen is opened under local anæsthesia, it can be demonstrated that palpation, squeezing with an ovum forceps, and even the injection of enough saline solution to distend its capsule, cause no pain. It is suggested that so-called ovarian pain arises in the extension of the parametric tissue which spreads in between the leaves of the broad ligament.

Pain arising in the pelvic organs, including the bowel, and the parametric tissue, can be abolished, even if only for the time being, in three distinct and separate ways:

(1) By infiltrating the ilio-hypogastric and ilio-inguinal nerves with a local anæsthetic.

(2) By infiltrating the parametric tissue with lignocaine. Pain caused by the injection is of course transitory, but it may "shoot" into the renal angle, into the hypochondrium and down to the knee, and this phenomenon is most striking.

(3) By cauterizing the internal os uteri with the silver stick.

The first procedure anæsthetizes mainly somatic nerves, the second autonomic nerves, while the third overstimulates autonomic nerves.

Further, uterine pain, indistinguishable from dysmenorrhœa, can be provoked by delivering a faradic current to the endocervix or endometrium, of so weak an intensity that it cannot be appreciated on the skin of the forearm or face. This pain can be relieved by raising an anæsthetic wheal, with either procaine or lignocaine, on the skin of the abdomen, in the midline, about 1½ in. (3·8 cm.) above the symphysis pubis. As the intensity of the current is increased a wider area of cutaneous anæsthesia is needed to abolish the pain. A point is soon reached when the pain cannot be abolished, but it is nevertheless referred to the same cutaneous area although it is completely anæsthetic. It is likewise easy to abolish the pain of dysmenorrhœa by raising an anæsthetic wheal on the same cutaneous area of the lower abdomen.

Before presenting conclusions it is worth referring to certain phenomena which may be associated with cauterization of the internal os uteri with the silver stick. In the first place autonomic nerves, other than those which mediate pain, may be stimulated. The woman

may not experience any pain as the result of this procedure, at any rate in the first instance. She may, however, vomit, and become covered with a cold sweat, while her pulse-rate may fall to about 40 a minute and her blood pressure to about 80/50 mm.Hg. This denotes a well-recognized physiological state in which the muscle capillaries are dilated and the venous return to the heart is severely diminished.

Apart from these rather frightening phenomena, which never occur if the patient is satisfactorily under the influence of self-induced trilene analgesia, it may be observed that cauterization of the cervix is remarkably efficacious in relieving frequency and urgency of micturition and stress incontinence of urine, provided no gross mechanical factors are operating.

In a healthy woman who complains of no pain at all, cauterization of the cervix provokes pain in the mid-line which spreads over the lower abdomen. If a woman complains of pain in one or other iliac fossa, this treatment frequently exacerbates her pre-existing pain, and is experienced nowhere else. If the sole reason for the cauterization is lower sacral backache, it may provoke an increase in the backache, but usually causes lower abdominal pain. If, however, the ilio-hypogastric and ilio-inguinal nerves are then infiltrated with a local anæsthetic, the abdominal pain is abolished and the backache becomes unmasked. This phenomenon of unmasking of pain can be most frequently demonstrated during labour.

It may also be observed that cauterization of a sinus in the vault of the vagina, subsequent to total abdominal or vaginal hysterectomy, may not only cause the same pain as cauterization of the cervix, but may cure long-standing and intractable abdominal pain. One such patient was so cured of severe pain in the right iliac fossa, of twelve years' duration, for which she had suffered four operations; appendicectomy, ventral suspension, oophorectomy, and finally, total hysterectomy. One patient complained, not only of dyspareunia, but of severe vomiting immediately after intercourse. A Mersilene ligature, left after vaginal hysterectomy, was removed, and she had no further trouble.

The practical claim which emerges from this very brief report is that iliac fossa pain, lower abdominal pain, dysmenorrhœa (both primary and secondary), dysuria, painful defæcation, and even pain in the hypochondrium and renal angle, together with frequency and urgency of micturition and stress incontinence of urine, may, in a high percentage of cases, be cured by cauterization of the internal os uteri with the silver stick, combined with the intelligent use of a local anæsthetic.

Injection of a local anæsthetic into the sacro-iliac ligaments may not only relieve backache, but also iliac fossa pain on the same, or even on the opposite side. Relief of pain may, moreover, serve to regularize the periods. The approach to the problem is constantly changing and more recently lignocaine has been used for infiltrating the ilio-hypogastric and ilio-inguinal nerves, and for injection into the parametric tissue. It is possible that these simple procedures may often be applicable in lieu of cauterization of the cervix, and they would clearly be of inestimable value in the presence of chronic inflammatory conditions (should cauterization of the cervix be contra-indicated) and after hysterectomy. Some of the results obtained have been quite dramatic, and dysmenorrhœa and urge incontinence of urine have been "cured", for at any rate some time, by the former procedure. It is, however, at present too early to assess the permanent value of these techniques. A number of cases of dysmenorrhœa have, however, been permanently cured by injecting an appendix scar, or a tender area in the abdominal wall, with a local anæsthetic. It must further be remembered that even an ordinary curettage in a multigravida may suffice to cure pain and even stress incontinence of urine.

Infiltration of the ilio-hypogastric and ilio-inguinal nerves with lignocaine is, moreover, useful in relieving acute lower abdominal pain associated with tubo-ovarian inflammation and other acute conditions. The same local anæsthetic, suitably injected, abolishes the pain of a Bartholin's abscess.

Further, the injection of a local anæsthetic can be used to differentiate between pain arising in the pelvis and appendicitis, while injection of lignocaine into the parametric tissue makes it possible to distinguish clearly between a small tubo-ovarian mass and spasm in the adnexa.

The pain signals are so elaborated in the cerebral cortex that they bear little resemblance to the final image or pattern. The pain image or capacity is compounded of imagination, fear, and such environmental factors as the lurid press, the cinema, aspirin and even the health service. We know, too, that advanced malignant growth, extensive endometriosis or massive adhesions may be present in the pelvis without causing pain, and conversely that severe and crippling pain may be associated with apparently normal pelvic organs.

It is suggested that pelvic pain may arise because of insults, either to the cerebral cortex, or to the pelvic organs and may be cured either by central suggestion (including hypnosis), or by overstimulating or anæsthetizing pelvic sympathetic nerves. It follows that surgical intervention, which is not always successful, should be used only as a final resort in the treatment of pain unassociated with detectable changes in the pelvic organs.

DISCUSSION ON THE EPIDEMIOLOGY OF CANCER

Dr. J. Knowelden:

Cancer in Kampala

It has been widely held that the pattern of cancer in Africans was different from that in white races, in particular in the high incidence of primary liver cancer, but it was also thought that in general malignant disease was rare in Africans. Dr. J. N. P. Davies, Professor of Pathology, and his colleagues at the Makerere College Medical School in Uganda, with the support of the British Empire Cancer Campaign, set up the Kampala Cancer Registry with the object of providing reliable evidence from the surrounding Mengo District to check these beliefs. I was invited to Uganda for a period of two months early in 1955 to see the registry and to advise on its future development.

The Registry was set up initially as a retrospective study of the Kampala hospital records in 1952 and 1953, but since 1954 it was reorganized as a current registry of in-patients. These hospitals—Government African, Asian and European and two large Mission hospitals—make Kampala the main hospital centre as well as commercial focus for the country. The quality of the medical information obtained is high, is backed by the Government and Medical School pathological departments and, as it is provided by a few clinicians only, is probably more uniform than would be found in a larger registry. The main problems lie rather in recording the identification particulars of the patients. The sick African, like his counterpart here, is liable to go the rounds of hospitals if he thinks he has not got satisfaction, but he confuses the trail by being unconcerned how he spells his name. A careful check has to be made to prevent duplicate entries of the same case from the different hospitals. It is common experience, too, that many Africans have little idea of their age, and even educated Africans have great difficulty in estimating accurately the age of their own tribesmen. Consequently rather crude approximations have often to be accepted. Finally, it is often difficult to establish the true place of residence, particularly if the patient is an immigrant from such distant places as the Belgian Congo and still speaks an unfamiliar dialect.

As a guide to the working of the registry we made a provisional analysis using the cases registered in the three years 1952–54 and the data from the 1948 census of Uganda. The data on cancer in the Asian and European populations is so scanty that I will deal entirely with the African picture. Table I shows the average annual age-specific incidence rates in

TABLE I.—INCIDENCE OF CANCER, ALL TYPES, IN MENGO DISTRICT, 1952–54
(Average annual rates per 10,000)

Age (years)	Males		Females	
	Cases	Rate	Cases	Rate
1–5	6	0·39	8	0·51
6–15	20	0·69	10	0·46
16–45	201	2·40	171	2·87
46 and over	193	9·09	101	6·60

TABLE II.—RELATIVE INCIDENCE OF CANCER, ALL TYPES, IN DIFFERENT PARTS OF MENGO DISTRICT, 1952–54

	No. of cases Registered	Expected	Regd./Expd. %
Males			
Kyadondo ..	167	64·2	*260*
Busiro and Kyaggwe	118	148·5	*79*
Other Sazas	135	207·3	*65*
Females			
Kyadondo ..	98	41·6	*236*
Busiro and Kyaggwe	96	97·4	*99*
Other Sazas	96	151·0	*64*

each sex for all types of malignant disease. The age-groups used were determined by those reported in the census, 1–5 years is childhood, 6–15 years the age at which children help in minding cattle or in domestic tasks, 16–45 years adult working life and 46+ old age—I have omitted the infants as hardly any cases were reported in this youngest group. The cheering picture was obtained that at least there was an age-gradient and perhaps our crude age-groups were meaningful.

The country is divided into numerous sazas, or counties, each under a native chief, Mengo District having 12 such sazas. We applied the age-specific incidence rates for the whole of

Mengo District to the census populations of each saza to obtain the expected number of cases which we then compared with the number registered among residents of these areas. We found wide variations in reported incidence as indicated by the ratios of registered to expected cases for each saza. I have summarized the pattern in Table II by showing Kyadondo separately (the saza in which Kampala lies), Busiro and Kyaggwe together the two nearest to Kyadondo with easiest communication with Kampala, and the remaining nine as the third group. In both sexes Kyadondo had about 2½ times the expected incidence, Busiro and Kyaggwe about average for the whole District and the remaining sazas lowest incidence. We considered whether these differences might have been caused by changes in population distribution since 1948 or by over-reporting of Kyadondo addresses by temporary residents, but eventually concluded that these factors could not be responsible. Instead we believe that easy access to Kampala hospitals by Kyadondo residents, and possibly their greater sophistication, gave better reporting than we could expect from a more distant entirely rural population. It is, therefore, proposed that the Register in future concentrates on this saza and takes special steps to check on such details as the stated residence of patients.

In Table III I have attempted a comparison between incidence in Kyadondo in 1952–54

TABLE III.—COMPARISON OF INCIDENCE OF CANCER, ALL TYPES, IN KYADONDO, 1952–54, AND IN DENMARK, 1942–44

(Average annual rates per 10,000)

Kyadondo		Denmark	
Age	Rate	Age	Rate
	MALES		
1–5	0·5	0–4	1·62
6–15	2·7	5–14	0·85
16–45	6·0	15–44	4·43
46+	24·3	45–54	22·57
	FEMALES		
1–5	1·6	0–4	1·08
6–15	0·3	5–14	0·64
16–45	7·0	15–44	8·19
46+	15·3	45–54	35·72

and in Denmark in 1942–44, as reported by the Danish Registry. There is a surprising similarity in male rates for the age-groups (these are not identical but are sufficiently close not to disturb this comparison): and in females the chief difference is in the oldest group. Some under-reporting in old women is to be expected as it appears to be general for them not to report to hospital when sick so readily as men of the same age. I was told also that uterine cancer was rarely seen until a specialist gynæcological unit was started at Mulago, but is now increasingly registered. It may be that these cancers are still under-reported.

As a final picture of the results being obtained I have compared the Kyadondo and Danish incidence in certain broad selected sites. To do this I have applied the Danish age-specific rates for each cause to the Kyadondo population and have shown in Table IV the total thus

TABLE IV.—COMPARISON OF INCIDENCE OF CANCER OF SELECTED SITES IN KYADONDO, 1952–54 WITH THAT EXPECTED AT DANISH RATES, 1942–44

	Males		Females	
Site	Registered cases	Expected cases	Registered cases	Expected cases
Skin	14	10·5	4	5·9
Gastro-intestinal ..	18	35·4	10	20·1
Liver	26	2·0	2	1·9
Kidney, bladder, &c.	19	13·1	2	2·0
Penis	11	1·2	—	—
Breast	—	—	9	30·7
Ovary and tubes ..	—	—	12	10·6
Uterus	—	—	28	43·5
Lymphatic system ..	22	10·2	4	5·4

expected in Kyadondo with the numbers observed. Here the outstanding differences are an excess of liver and penile cancer in men, a deficiency of gastro-intestinal cancer in both sexes, and a deficiency of breast cancer in women.

These results are provisional and too much emphasis must not be placed on them. The Kampala registry is continuing for several years and it is hoped to have recent and reliable census data available by 1958 when several years' data will have been accumulated. I hope I have said enough to indicate the considerable problems involved in the work Dr. J. N. P. Davies and his colleagues have undertaken, and also the excellent promise of valuable information which has been afforded by their initiative.

Dr. Alice Stewart:

A Current Survey of Malignant Disease in Children

The decision to make an environmental survey of leukæmia in childhood (by interviewing parents after the death of the child) was taken after a close scrutiny of official vital statistics (Hewitt, 1955) had shown the nature and extent of the rise in the death-rate at all ages (Fig. 1) and at ages under 5 (Fig. 2). The unusual peak of mortality in the 2nd and 3rd years of life (which has been more marked in recent years) was the main reason for restricting the survey to young children and for focusing attention on antenatal X-ray histories. Children who had died from other cancers were originally included in the survey as a contrast group, but subsequent examination of vital statistics has shown that for young children, these deaths also have an unusual age distribution (Fig. 3).

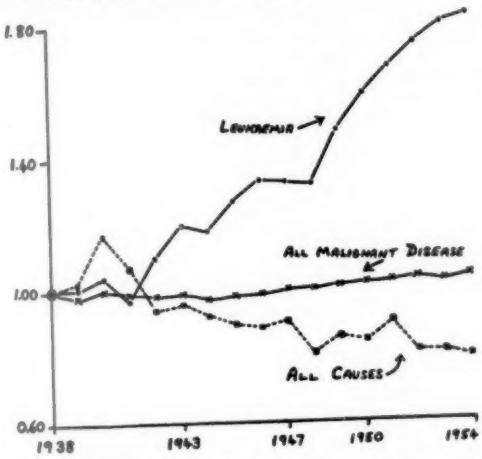

FIG. 1.—Course of the comparative mortality index for certain causes of death, 1938=1·00.

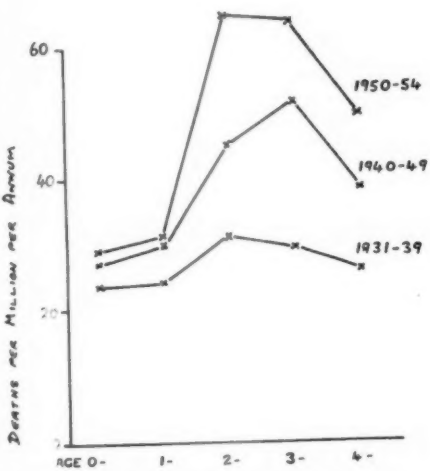

FIG. 2.—Mortality of young children from leukæmia in three different periods.

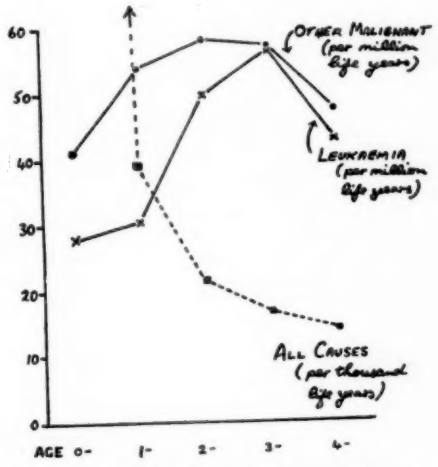

FIG. 3.—Mortality from certain causes at ages under five, England and Wales, 1940–1954.

Even the field work of the survey is not yet completed, but all Local Authority Health Departments in England and Wales are co-operating and an attempt is being made to cover

all cancer and leukæmia deaths under 10 years of age reported in the three years 1953–55. These comprise:

	Cases
Leukæmias	794
Neoplasms of brain and spinal cord ..	269
„ „ kidneys	155
„ „ suprarenals	136
„ „ lymph nodes	133
„ „ other sites	193
Total	1,680

For each of the cases included in the survey there will be a live control matched for age and sex, but otherwise picked at random from a local list of births. Thus far, most of the control children have been first choices, but removals, infant deaths, &c., have occasionally necessitated taking several names from a birth list. Unless they have moved out of the Local Authority area since the child's death, the parents of each case-control pair are being interviewed by one and the same doctor. The questionnaires for the children who have died are designed to elicit information about the child's health before the onset of the fatal illness, and the mother's health before and during the relevant pregnancy. All investigations and treatments are recorded, and wherever possible X-ray data are checked with hospital notes. A note is also made of any cases of leukæmia and malignant disease in the family, any degree of consanguinity between parents and grandparents, and certain features of the child's diet and home background. The schedules for the controls ensure that the same facts are obtained up to the age when the corresponding case first showed signs of the fatal illness.

By November 1, 1956, only 1,072 case-control pairs had been interviewed. The records of these interviews still await detailed analysis, but preliminary inspection has revealed two points of considerable interest. In the first place a history of irradiation *in utero* (i.e. an ante-natal *abdominal* X-ray) was obtained nearly twice as frequently from the mothers of children who had died from leukæmia or cancer as from the mothers of live controls (*see* Table I). Secondly there were, among the 515 cases of leukæmia, 15 children who were mongolian idiots.

TABLE I.—MALIGNANT DISEASE IN CHILDHOOD AND DIAGNOSTIC IRRADIATION *In Utero*

Group	Number of children	Children irradiated *in utero*	
		Number	Per cent
Controls	1,072	79	7·4
Cases of:			
Leukæmia ..	515	63	12·2
C.N.S.	168	20	11·9
Renal	103	16	15·5
Neuroblastomas	91	18	19·8
Lymph nodes ..	70	6	8·6
All other sites	125	20	16·0
All cases of malignant disease	1,072	143	13·3

The reasons for the excess of "irradiated fœtuses" among the cases will remain uncertain until a more detailed examination of the records has been made. But it is already clear that the difference between the cases and controls in this respect is not due to differences in birth, rank or social class nor to differences in maternal age. The most likely explanation is that total body exposure to small doses of ionizing radiations shortly before birth causes a significant increase in the risk of developing leukæmia or cancer in childhood (Stewart, Webb, Giles and Hewitt, 1956). No explanation of the excessive liability of mongols to leukæmia can be offered at this stage, but the association between the two diseases appears to be independent of any history of irradiation and has already been noted by other workers (Krivit and Good, 1956; Merrit and Harris, 1956).

DISCUSSION ON TUBERCULIN SENSITIVITY

Dr. A. B. Paterson (Weybridge):

The Tuberculin Test in Tuberculosis-free Cattle

It has long been known that reactions to tuberculin can occur in cattle free from tuberculosis and the existence of these so-called non-specific reactions was indicated by Bang and by Hastings at the beginning of the century. The use of high doses of tuberculin of increased potency in the intradermal test, and decrease in the incidence of tuberculosis both helped to increase difficulties of interpretation, and, in addition, about 1925 there came a wider appreciation that mycobacteria other than those of bovine type might sensitize to mammalian tuberculin (Bang, 1936; Hastings, 1912–13; Plum, 1925). Since then much work has been devoted both to causes of heterologous sensitizations and to aids in the interpretation of reactions to mammalian tuberculin.

One of the most valuable aids has been the use of avian tuberculin, and since 1940 it has been used in the United Kingdom simultaneously with mammalian tuberculin in all official tests connected with the attested herds scheme (Ministry of Agriculture, 1942). The "comparative" test permits interpretation of reactions to mammalian tuberculin in herds believed to be free from tuberculosis—such reactions, if accompanied by strong reactions to avian tuberculin, must be interpreted with caution after taking fully into account the history of the herd and its environment.

I shall give briefly the known causes of non-specific tuberculin sensitization in cattle, and, in view of the current interest in human medicine in geographical distribution of tuberculin sensitivity, I shall present a picture of its incidence and occurrence in cattle in two areas of England.

Causes of Non-specific Sensitization in Cattle

(1) *Avian type tubercle bacilli* may produce tuberculin sensitivity without lesions, the sensitivity disappearing with removal of the infecting source. Occasionally lesions or even generalized tuberculosis may occur.

Sources of avian tubercle bacilli are:

(*a*) Tuberculous poultry; (*b*) swine (of little importance); (*c*) birds other than poultry—pigeons, gulls, sparrows, starlings, wood-pigeons, pheasants and crows (pigeons, wood-pigeons and sparrows may harbour avian type tubercle bacilli apparently without having contact with infected poultry); (*d*) rats.

The avian type tubercle bacillus can be transmitted by such agencies as fly larvæ (Feldman, 1938).

(2) *M. johnei.*—Well known as the cause of a chronic enteritis in cattle (Johne's disease) and allergically related to the avian type of tubercle bacillus. Experimental and natural cases of Johne's disease show early sensitivity to avian tuberculin which disappears with progress of the disease.

(3) *So-called "skin tuberculosis".*—This is a benign disease of cattle in which lesions commonly occur on the skin of the legs as nodular granulomata, which may contain a yellowish pus. The lesions contain uncultivable mycobacteria (Robertson and Hole, 1937; Hole and Hulse, 1939). Sensitivity, to mammalian rather than avian tuberculin, has been produced experimentally in cattle inoculated with lesion material.

(4) *Human tubercle bacilli*, derived from infected human subjects, produce sensitivity to mammalian tuberculin which disappears with removal of the source of infection and is less marked on re-test (Stenius, 1938).

BCG and the vole bacillus produce sensitivity to mammalian tuberculin.

(5) *Saprophytic mycobacteria.*—It is debatable whether such saprophytic species as *Mycobacterium phlei*, *M. smegmatis*, &c., can render cattle sensitive to tuberculin. Experimentally they sensitize cattle only when injected along with an oily adjuvant. Whether intermediate types such as *M. ulcerans* or *M. balnei* are of importance is not known.

(6) *Organisms other than mycobacteria.*—*Actinobacillus lignieresi* and *Br. abortus* have been reported as causal agents of sensitivity to tuberculin in cattle in the field, but sensitivity could not be produced experimentally with *Corynebacterium pyogenes*, *Actinomyces bovis*, *Actinobacillus lignieresi* (Buxton and Glover, 1939). Non-specific sensitivity is apparently not produced in infections with the liver fluke, *Fasciola hepatica*; during migration of larvae of the warble fly, *Hypoderma bovis*; or by hydatid cysts. It does not result from vaccination with avirulent *Brucella abortus* (Strain 19 vaccine), or from histoplasma infection.

(7) *Physiological causes and natural hypersensitivity.*—Cattle apparently do not readily develop tuberculin type sensitivity of high order.

(8) *Reactions caused by tuberculin itself.*—Phosphate-diluting fluids apparently potentiate a reaction, but produce very small reactions when injected alone.

Despite the many investigations of non-specific reactivity to mammalian tuberculin, it is difficult to obtain a clear picture of the degree to which it occurs, and my colleague, Miss Hebert, and I therefore attempted some quantitative arrangements of data obtained from the records of routine tuberculin tests in herds tested under the "Attested Herds Scheme". Samples of 100 herds in Berkshire and of 200 herds in Cumberland were taken. All herds in both samples had been accepted as free from tuberculosis (Hebert and Paterson, 1955; Paterson and Hebert, 1957). Since the comparative test is always used, a contrast can be drawn between the reactivity to avian and mammalian tuberculins in the two counties. The test itself comprises the intradermal injection of avian and mammalian PPD tuberculins at respective strengths of 0·5 and 2·0 mg./ml., each in a dose of 0·1 ml. Injections are made in the skin of the middle third of the neck, and measurements are made of the thickness of the double fold of skin at the injection sites before and 72 hours after injection. The difference, in millimetres, between the first and second measurements constitutes the degree of reaction.

The data were analysed and histograms and graphs prepared to illustrate (*a*) the percentage of animals giving different degrees of response to avian and mammalian tuberculin in the two areas, (*b*) variation in reactions in age groups, (*c*) influence of proximity of herds to woods and trees, (*d*) effect of altitude, (*e*) effect of geographical regions, (*f*) influence of "skin tuberculosis", (*g*) influence of sex, and (*h*) of some other factors.

[These histograms and graphs were shown on slides and are not reproduced here. The conclusions arrived at as a result of this study were discussed by Dr. Paterson.]

Frequency Distribution of Reactions

This study indicated that the degree of non-specific reaction to mammalian tuberculin in the two counties was the same but the reaction to avian tuberculin differed significantly. If the non-specific response to mammalian tuberculin parallels the avian reaction then the avian agency must be more efficient in Cumberland than in Berkshire.

Reactions of Age Groups

When the mean reactions of animals in the samples were arranged according to age, some striking similarities and differences were revealed.

(1) In both areas the response to mammalian tuberculin was always broadly parallel with that to avian tuberculin.

(2) In Cumberland avian reactivity rose rapidly to a peak at 4 years of age with a slight downward trend to 10 years of age. In contrast, in Berkshire a much higher peak was reached by 3 years, the higher reactivity being significantly different at ages of 1, 2, 3 and 4 years.

(3) In Cumberland, the curve of reactivity to mammalian tuberculin slowly rose to a peak at 8 years of age. In Berkshire cattle, the curve of reactivity started below the Cumberland curve, rose above it to a maximum at 3 years, crossed below between 5 and 6 years of age and reached a minimum at 9 years.

The curves for non-specific reactions to mammalian tuberculin suggest that either quality of the sensitizing agent or the mechanism producing sensitivity differs in the two areas.

Proximity to Trees and Woods

Smith (1955) has suggested that the incidence of non-specific reaction is higher in cattle in wooded regions than elsewhere and has related this to the presence of wood pigeons which are known to harbour mycobacteria closely related to the avian tubercle bacillus. The graphs for Berkshire support this suggestion but in Cumberland this is not so and factors other than woodlands appear to be of greater influence.

Effect of Altitude

Increasing altitude appears to decrease the incidence of non-specific reactions. The effect being more marked in Cumberland with altitudes of 1,000 ft. and over, than in Berkshire where altitudes rise to only 600 ft.

Effect of Geographical Regions within the Two Counties

In Berkshire, except for a rather higher reactivity to avian tuberculin in the Windsor region, there was little difference from area to area. In Cumberland there was a definite drop from the low-lying coastal land in the west to the higher areas in the east. Here altitude and regional effects go together. The altitude effect, for some unknown reason, is most marked in calves.

Skin Tuberculosis

The incidence was about 1% in both counties. Tuberculin sensitivity appeared at an early age and was more marked to mammalian tuberculin at all ages. The highest sensitivity appeared at an earlier stage than the maximum incidence of the disease.

Effect of Sex

Male animals in Cumberland had a higher degree of reactivity to avian tuberculin than those in Berkshire, probably because in Cumberland bulls are kept at pasture, whereas in Berkshire they are usually housed.

Other Factors Examined

Neither the keeping of pigs or poultry on the farm, nor the breed of cattle appeared to have any marked influence on the incidence of non-specific reactivity.

Conclusions

The picture of non-specific reactivity to mammalian tuberculin in this study confirms that such reactions are usually linked to reactivity to avian tuberculin which is almost certainly caused by *Mycobacterium tuberculosis* var. *avian* or the related *Mycobacterium johnei*. The difference in the data from the two counties as revealed by the graphs may be an indication of the relative incidence of these two agents in these counties. The major factor determining the development of non-specific reactions appears to be contact with a warm-blooded host infected with and excreting mycobacterium. Little is known of the influence of route of infection or of the quantity and frequency of the infecting dose on the products of non-specific reactivity. There is little evidence that saprophytic or intermediate types of mycobacteria are concerned; experimentally they can cause tuberculin sensitivity only when given in massive doses or in conjunction with an adjuvant substance. Organisms other than mycobacteria have been suspected only when a distinctive granulomatous type of lesion is produced (Paterson, 1956).

Dr. T. Francis Jarman (Medical Director, Mass Radiography Service, Welsh Regional Hospital Board):

Tuberculin Testing in the Control of Tuberculosis

When Robert Koch discovered tuberculin in 1890 great hope was placed in its possible usefulness as a therapeutic agent, a hope which proved to be unjustified. Von Pirquet in 1906 first described its use to detect persons infected with the tubercle bacillus.

The use of tuberculin for this purpose has been of the very greatest importance in the control of tuberculosis. There are, at present, two ways in which it is used—diagnostically in individuals and as an epidemiological technique in the study and control of tuberculosis in the community. Certain aspects of tuberculin testing have recently come much to the fore and it is with these that I propose to deal in some detail.

The Reliability of the Test

Myers (1946) declares that "as an epidemiological agent the test excels every other procedure" relative to tuberculosis. Meyer and others (1951) have shown that error in the

reading of the tests is very small. In the first survey in the Rhondda Fach, 1,228 tests were read by two observers for qualitative results and in only one case was there any discrepancy in the readings (Jarman, 1953).

Palmer and his associates (1950) first drew attention to the possibility of non-specific reactions to human tuberculin. In recent years 43 million tests have been carried out under the direction of the World Health Organization and its Tuberculosis Research Office. Their teams have paid particular attention of late to the problem of non-specific, or false positive, reactions. It appeared to them that methods similar to those employed by the veterinarians for the purpose of separating cattle with specific and non-specific tuberculin sensitivity might be used in the study of non-specific sensitivity in man (WHO Tuberculosis Research Office, 1955). Discrepancies in the frequencies of weak-dose and strong-dose reactors to human tuberculin in different geographical areas suggested that persons with strong-dose reactions could be regarded as having non-specific sensitivity. A special TRO team tested more than 3,000 persons with serial doses of both human and avian PPD tuberculin corresponding to 1, 10, and 100 T.U. Results from these comparative tests indicated that the tuberculin sensitivity in the populations studied must be caused by different sensitizing agents. The low-degree sensitivity was brought out more effectively by avian tuberculin and the high-grade sensitivity by human tuberculin. However, those with high-grade sensitivity (i.e. those reacting to a small dose) can undoubtedly be regarded as having specific sensitivity caused by infection with virulent tubercle bacilli. Positive reactions to either 5 or 10 T.U. can, therefore, be regarded, for practical purposes, as specific positive reactions (WHO Tuberculosis Research Office, 1955).

The need to develop a simple test which can be given by relatively untrained persons has led to the development of the multiple puncture test using undiluted Old Tuberculin (Heaf, 1951). Comparisons have been made between this test and the intradermal Mantoux method (Jarman, 1953). This work and recent studies by Gillis and Stradling (1957) on double observer reading of the tests illustrate the difficulty of establishing the lowest category of reaction to this test which can be considered as positive and which is reproducible. Nevertheless, the Heaf test has proved easy to administer and extremely valuable in practice and its use is increasing. Studies to compare the prevalence of positive reactors to the Heaf test in mass tuberculin testing with that obtained by using 5 T.U. by the intradermal technique might give useful information as to the possibility of non-specific reactions produced by the former.

Mass Tuberculin Testing as a Reflection of Tuberculous Infectivity in a Community

The percentage of positive reactors in different age groups presumably reflects the degree of tuberculous infectivity in a community and good evidence exists to support this. Recently, in the town of Monmouth the number of new cases of pulmonary tuberculosis notified rose sharply in excess of what was expected especially in the age group 15–20. A mass radio-

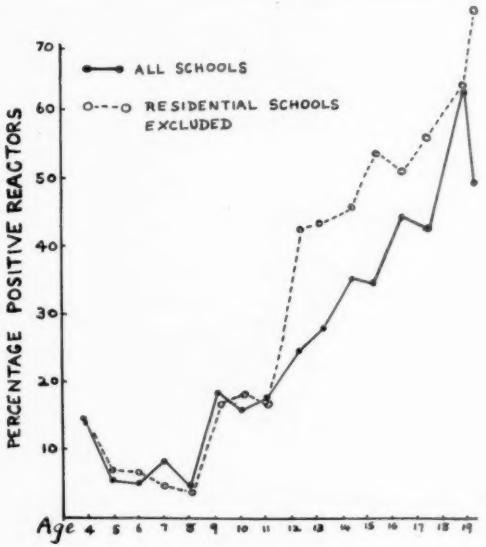

FIG. 1.—Results of tuberculin testin in Monmouth.

graphy survey of the total community type (Cochrane *et al.*, 1952) was therefore carried out and 89% of the population were X-rayed. The prevalence of active tuberculosis was highest in the age group 15–24, viz. 15 per 1,000 and this was to some extent reflected in the results of the overall tuberculin testing but became more evident when the residential schools were excluded (Abraham *et al.*, 1955) (Fig. 1). Tuberculin testing in the Calder Valley (Keidan *et al.*, 1952) when compared with that done in Leeds and in the Rhondda Fach shows how the excessive amount of non-respiratory infection in the Calder Valley was reflected in the prevalence of positive reactors (Fig. 2). Griffith (1956) showed that 35% of children aged

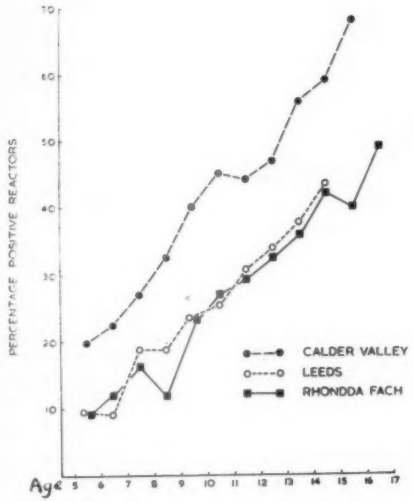

FIG. 2.—Results of tuberculin testing in the Rhondda Fach compared with those of the Calder Valley and Leeds.

5–13 from two schools in the docks area of Cardiff reacted positively to tuberculin testing whereas only 24% of children aged 12–13 from all other Cardiff schools were positive. The difference between these rates is reflected in the findings of mass radiography surveys in these districts (Welsh Regional Hospital Board, 1956). In the population of the docks area 8 new cases of pulmonary tuberculosis were discovered for every 1,000 persons examined in contrast to Cardiff where only 2 new cases were discovered for every 1,000 examined. Tuberculin testing can, then, be useful to ascertain the likely size of an existing tuberculosis problem, especially in relatively backward areas where mortality and prevalence are high. Benjamin (1955) has emphasized the importance of such survey techniques in India. In the mass tuberculin testing done during the International Tuberculosis Campaign the prevalence of positive reactors was used primarily for selecting persons for vaccination but the results also reflected the probable tuberculosis situations in the various countries. The frequency of positive reactors in the age group 7–14 years varied from 13% in Costa Rica to 75% in Hong Kong. The percentages were lowest in the American countries, highest in the Far East, and intermediate in the Near East and Africa.

The results of repeated tuberculin testing in a community can be extremely useful as a measure of progress in tuberculosis control and it is for this, amongst other reasons, that Myers *et al.* (1955) and Gedde-Dahl (1956) are opposed to the use of BCG in low prevalence areas such as Minnesota and certain regions in Norway. Myers and others (1955) have shown that tuberculin testing of grade school children once in ten years since 1926 has served as an accurate measure of the effectiveness of the tuberculosis control programme in Minneapolis. In 1929, 47·3% of the children reacted to tuberculin; in 1936, 18·9%; in 1944, 7·7%; and in 1954, 3·9%. The results of tuberculin testing in the two Rhondda Fach surveys also illustrate this (Jarman, 1955). At the time of the second survey the overall prevalence of infectious pulmonary tuberculosis had been reduced to a greater extent than in a "control" valley and this is shown in Figs. 3 and 4 and Table I. The results of follow-up testing in school children are shown in Tables II, III, IV and V. The most interesting feature in these tables is the high rate of reversion amongst the school children in the Rhondda Fach as compared with the control valley. It would be interesting to know if such reversion has been observed in cattle.

Tuberculin Testing as a Means of Detecting Source Cases

MacDougall and others (1953) tuberculin tested 3,798 school children between the ages of 3 and 9 years and discovered one previously unknown case of active pulmonary tuberculosis for every 237 tests performed. During 1955–56 in the town of Barry, Glamorgan, 60% of the population were X-rayed by the Welsh Mass Radiography Service. This survey was combined with tuberculin testing of the infant school population, and house contacts of positive reactors were persuaded to attend the unit for X-ray examination (Thomas, 1956). One new case of active pulmonary tuberculosis was discovered amongst the 49 tuberculin-positive children and one from the 290 adult contacts who were X-rayed. This amounts to one new case of active pulmonary tuberculosis discovered amongst adult contacts for every 1,404 tests carried out. The discovery, by radiography, of this one case amongst 397 adult contacts amounts to 2·5 cases per 1,000 examined, which is no more than the rate at which active cases are discovered by routine mass radiography. It would appear, therefore, that this was not a very profitable method of discovering new "source" cases in this town. Ritchie and others (1955), however, used this method in Belfast and found that the prevalence of active tuberculosis amongst adult contacts of tuberculin-positive children was three times as high as that amongst contacts of children who were tuberculin-negative. The usefulness of this case-finding method may be related to the overall prevalence of pulmonary tuberculosis in the community.

Tuberculin testing has been used as a method of discovering source cases by Gedde-Dahl (1952) in work which has become classical. He adopted the method of continuous testing of a whole community in the district of Kim, 100 miles north of Bergen between the years 1937 and 1944. Wherever and whenever a negative reactor was found to have converted to positive a "tuberculosis situation" was deemed to exist and was intensively investigated until the source was discovered. From 272 persons who converted during the period of observation 73 (26%) "intradomiciliary", 130 (48%) "extradomiciliary" source cases were discovered and 70 (26%) could not be traced. This "tuberculin matriculation" technique is, however, applicable to small isolated rural communities rather than densely crowded urban industrial populations.

Use of the Tuberculin Test in BCG Work

In mass BCG vaccination programmes in 26 countries between 1951–1953 in the International Tuberculosis Campaign 43 million persons were tuberculin tested and 16 million vaccinated (WHO Tuberculosis Research Office, 1955). In all cases a single intradermal tuberculin test with 5 T.U. of PPD prepared at the Statens Seruminstitut, Copenhagen, was used as the initial test to separate the infected from those not infected and requiring BCG. The test was read at three to four days and a reaction of less than 5 mm. of induration was considered "negative". BCG-induced tuberculin sensitivity is a problem of considerable theoretical and practical significance. A research programme has been designed by the U.S. Public Health Service (1955) to find out whether the potency of the vaccine, size of the vaccinal lesion, and size of the post-vaccination intradermal tuberculin reaction are related to induced immunity. Studies so far tend to show that immunity is not related to the size of the vaccinal lesion, as a large reaction can be produced by relatively impotent heat-killed BCG, but that it is related to the size of the post-vaccination tuberculin reaction (Tuberculosis Programme, Public Health Service, U.S.A., 1955). A potent vaccine has been shown to produce allergy about as strong as that produced by natural infection which does not appear to wane after intradermal vaccination (WHO Tuberculosis Research Office, 1955). These findings are obviously of the greatest importance, especially in areas of high prevalence.

Use of the Tuberculin Test as a Method of Case Finding amongst Those Actually Tested and Found Positive

Expected immediate morbidity is greater in tuberculin-positive than in tuberculin-negative groups (Palmer and Shaw, 1953). This is especially true of recent converters. In the

Rhondda Fach survey the annual morbidity rate amongst children originally positive was 4·3 per 1,000 in contrast to 1·4 per 1,000 amongst those originally negative (Jarman, 1955). D'Arcy Hart and his colleagues (1956) have pointed out that in the Medical Research Council's BCG trials children with strong positive reactions at the outset were four times more likely to develop tuberculosis in the next two to three years than those with weak reactions and one and a half times more likely to do so than those with negative reactions who were left unvaccinated.

Bentley (1955) regards the positive tuberculin reaction in very young children as of supreme diagnostic importance and attacks the conception that "infection but no disease has occurred". He recommends that all infected children under 2 years of age should be given a course of PAS and INAH irrespective of the presence, absence, or extent of radiological shadows and that antibiotics should be given at any age to recent converters. Not all clinicians will agree with this; it is mentioned to give point to the contention that tuberculin sensitivity is a phenomenon which can have valuable diagnostic significance.

Use of the Tuberculin Test for Limited Research Purposes

Recently Carpenter and others (1956) have used the results of tuberculin testing in a community as one amongst other methods of assessing the tuberculous infectivity of progressive massive fibrosis in coal-miners. This study showed that in homes where there is a man with PMF whose disease is progressing the percentage of Mantoux-positive children is unlikely to exceed by more than 10% the proportion Mantoux-positive from comparable homes but without this possible risk of infection. Miller (1953) carried out a similar study relating to pottery workers and found that the incidence of positive reactors amongst those whom it seemed might be particularly exposed to infection from workers with tuberculoconiosis was no greater than amongst those not so exposed.

All the ways described in this paper in which tuberculin sensitivity in man has been used in the fight against pulmonary tuberculosis surely demonstrate that it is, and remains, a really formidable weapon in the hands of epidemiologists and clinicians alike.

Section of Orthopædics

President—E. STANLEY EVANS, C.B.E., F.R.C.S.

[*November* 6, 1956]

Osteoid Osteoma of the Transverse Process of the Fifth Cervical Vertebra.—F. GODSALVE WARD, F.R.C.S.

Peter F., aged 11 years.

At the age of 8 years he presented with a year's history of increasing pain in the neck which was rigid on examination. He was treated as a case of cervical caries with a Minerva plaster followed by a Robert Jones frame on account of subsequent spasm in the left hip. In January 1955 the lesion in the neck was explored and after removal of ivory hard bone a cherry red core was curetted which had the histological appearances of osteoid osteoma. The X-rays show the evolution of the tumour which had become painless by the time that the operation was done.

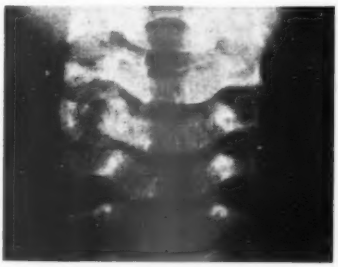

FIG. 1.—29.12.53.

FIG. 2.—10.12.54.

The last comprehensive survey of osteoid osteoma was by Golding (1954) who reported 178 cases from the literature of which 19 were in vertebræ, and added 20 of his own including 2 more vertebral cases. Jackson (1953) had found 217 in the literature with 19, presumably the same 19, in vertebræ, so the vertebral incidence is about 1 in 10 of all cases of osteoid osteoma. One of Jaffe's (1935) original 5 cases was in the spinous process of C7.

A special feature of some of the spinal cases has been the hypertrophic change in the adjacent joint first pointed out by Mary Sherman (1947) which may encroach upon the intervertebral foramen. One case in the vertebral arch of L2 reported by Fagerberg and Rudström (1953) presented just like a "disc sciatica" and Jackson's (1953) case in the arch of L8 was diagnosed only at operation for a supposed neurofibroma of the 8th dorsal nerve root. The case reported by Campos (1946) in the spinous process of C4 was first diagnosed as tuberculous and had a mild leucocytosis and an E.S.R. raised to 33 mm. (Westergren) in the hour but tuberculosis was later disproved by a negative Mantoux test.

Two Cases of Sarcoidosis with Peripheral Joint Manifestation.—R. A. BREMNER, F.R.C.S., for P. H. NEWMAN, D.S.O., F.R.C.S.

Case I.—C. F., male, aged 40. Electrical engineer.

History.—First noticed swelling of the second toes of both feet in 1941, and a little later a discoloured swelling of his right cheek. Biopsy was carried out and a histological diagnosis of sarcoidosis made. Gold therapy was tried, but abandoned owing to the development of nephritis.

Subsequently he remained fairly well, apart from a complaint of persistent catarrh, until 1950, when his fingers began to swell and become stiff. This has gradually progressed over the past five years; the patient says more rapidly recently. Two courses of deep X-ray therapy to the hands were tried in 1950 and again in 1955 without improvement.

The patient came under the care of the Middlesex Hospital in September 1956. The main complaints then were of progressive swelling, stiffness, and clumsiness of his fingers, and of persistent catarrh, coupled with general malaise.

On examination.—The hands showed soft fusiform swellings of the fingers and thumbs, although the right thumb was relatively little affected, of such extent that a fist could not be made with either hand, and fine movements of the fingers were seriously impaired.

X-rays: Hands and feet showed typical bone changes of sarcoid; chest showed typical hilar lymphadenopathy.

Blood.—E.S.R. 8 mm. in first hour (Westergren). Hb 106% (15·4 grams%). W.B.C. 4,900: differential count normal. Serum calcium 9·3 mg.%. Plasma phosphate 3·5 mg.%. Total protein 8·3 grams% (albumin 4·1, globulin 4·2 grams%). Electrophoretic pattern normal.

Blood urea 37 mg.%. Mantoux reaction negative. Renal investigations and barium meal revealed no abnormality.

Biopsy of nasal mucosa positive for sarcoid.

Treatment and progress.—Prednisolone in a dosage of 5 mg. q.i.d. had been given for two weeks with marked improvement in finger function.

Case II.—T. P., aged 41. Electrical engineer. (Dr. Paul Strickland's case.)

History.—In 1948 a routine X-ray showed a bilateral hilar lung lesion suggestive of sarcoidosis. The patient was at that time symptom-free. In 1952 he developed a painful swelling of the proximal phalanx of the ring finger of his left hand, which gradually increased.

X-ray of the hand showed typical sarcoid bone lesions. (These changes have not altered during four years of observation in spite of marked improvement in the clinical picture.)

Blood: E.S.R. 5 mm. in first hour (Westergren). Serum calcium 10 mg.%. Total protein 7·7 grams% (albumin 4·5, globulin 3·2 grams%). Electrophoretic pattern shows an increase in the alpha-2 fraction. Mantoux reaction negative. Kveim test positive.

Biopsy of left axillary gland (1954) positive for sarcoid.

Treatment and progress.—In 1954 a course of ACTH was given for six weeks with slight benefit. In 1955 skin lesions on the hands developed. Cortisone orally was given for twelve months with improvement in the range of finger movement and diminution of the swelling. Some fading of the skin plaques also took place.

In June 1956 prednisolone in a dosage of 5 mg. q.i.d. was commenced with marked improvement. Reduced to 5 mg. t.d.s. on 1.8.56, and again to 5 mg. b.d. on 26.9.56.

Present condition.—Slight thickening of the soft tissues of the ring finger of the left hand, and faded remnants of skin plaques are visible on the dorsum, but a good fist can be made, and the maintenance dose of prednisolone, 5 mg. b.d., keeps up the good results. The patient does full work at his previous employment.

Lipoma Causing a Posterior Interosseous Nerve Lesion.—A. D. THOM, M.B. (for R. H. MAUDSLEY, F.R.C.S.).

Mrs. F., aged 47, a housewife, had since January 1956 noticed a progressive weakness of extension of the right thumb and fingers with some aching down the lateral aspect of the forearm.

On examination (7.8.56).—There was an almost complete right posterior interosseous nerve paralysis. There was $\frac{3}{4}$ in. wasting of the forearm and no obvious sensory changes. There was a diffuse palpable swelling present in the outer aspect of the antecubital fossa. There was no other relevant abnormality.

Investigations.—X-ray of elbow showed a radiotranslucency resembling a gas bubble, anterior to the neck of the radius. Blood and urine examinations normal. E.S.R. 12 mm./first hour (Westergren). W.B.C. 8,800. Hb 86% = 12·8 grams%.

A provisional differential diagnosis was made of: (1) Lipoma. (2) Neurofibroma.

9.8.56: As the paralysis was progressing an exploratory operation was undertaken

Through a Kocher's incision the posterior interosseous nerve was found stretched across a fatty mass deep to the supinator. The nerve was bluish in colour and appeared cystic and degenerate.

On reflexion of the supinator the mass appeared to be a lipoma closely applied to the head and neck of the radius and extending into the elbow-joint, where the mass was whiter and of a firmer consistence. On removing the mass the anterior surface of the neck of the radius was seen to be bare of periosteal covering and the rim of articular cartilage of the head had been eroded.

Histology.—Fibrolipoma.

Progress.—Rapid progressive recovery of the paralysed muscles.

Comment.—Peripheral nerve lesions due to lipomata are rare. In the 2 cases previously described in this area the lipoma lay in the substance of the supinator muscle (Campbell and Wulf, 1954; Richmond, 1953).

An Unusual Patella.—G. O. TIPPETT, F.R.C.S.

A woman now aged 70, in 1940 fell on her left knee bruising it. She rested the knee for some weeks at home then resumed her employment as a part-time cleaner. Her knee has caused no trouble until the last few years when she considered that the patella had commenced to enlarge.

FIG. 1.

First seen June 1956; the patella was greatly enlarged, rough and irregular, nearly the size of an orange and fixed to the tibia so that the patella moved with the tibia in flexion. In spite of this she had a full range of movements and after a few physiotherapy treatments she had no pain and the power and function of the knee returned to normal. The X-ray showed gross enlargement of the patella with obvious old fragments of the original patella surrounded by a mass of new irregular bone formation suggesting an old comminuted fracture of the patella with much local hæmatoma formation which has slowly undergone ossification and moulded itself around the patella fragments (Fig. 1).

Undiagnosed Lesions of Both Tibiæ.—R. H. METCALFE, M.D., M.Chir., F.R.C.S.

J. S. Born 29.11.45.

21.6.55: Presented with a history of three weeks' pain and swelling in right knee. On examination knee was hot and slightly swollen but there was no fluid in the joint and movement was painless. X-ray: Increased density of upper epiphysis of right tibia, probably a form of osteochondritis (Ritter's disease)—may be a chronic inflammatory condition.

2.7.55: No complaint. 100% function.

18.8.55: Knee now definitely swollen; boy has a slight limp. Right upper tibial condyle is tender. Control X-ray: no change (Fig. 1). Also pain in left knee. Right ankle and big toe. X-ray showed nothing abnormal.

FIG. 1.

FIG. 2.

FIG. 3.

A

B

FIG. 4.

19.8.55: Admitted Queen Mary's Hospital for Children, Carshalton. Still has 100% function.

22.8.55: X-ray: In addition to sclerosis of upper right tibial epiphysis, there are abnormalities in lower poles of both patellæ suggestive of osteochondritis. Mantoux test negative in all dilutions. E.S.R. 30 mm. in first hour (Westergren). Treated on tip up bed with reduction of heat and swelling.

17.10.55: Walking in right patten-ended Thomas's caliper with raised left boot.

11.11.55: Control X-ray: Similar sclerosis has appeared in upper left tibial epiphysis. Still no change in associated metaphysis (Fig. 2).

19.12.55: Discharged home walking in right patten-ended caliper.

15.3.56: Control X-ray: Commencing rarefaction of metaphysis upper end of both tibiæ. This change supported diagnosis of bilateral osteochondritis upper tibial epiphysis (Ritter's disease).

17.5.56: Control X-ray: Condition in upper end both tibiæ slowly progressing. Half-inch lengthening right leg. Patten-ended caliper discarded.

5.7.56: Control X-ray: Upper tibial epiphyses appear to be re-vascularizing.

20.7.56: Control X-ray of knees: showed *for first time* an abnormality in right tibial shaft (Fig. 3).

Diagnosis: Syphilis. W.R. of boy and both parents negative.

14.9.56: Biopsy: Reticulosarcoma involving bone and periosteum.

19.9.56: Discharged home walking normally.

6.11.56: Case shown at Orthopædic Section, Royal Society of Medicine. The following possible diagnoses were made:

(1) Dual pathology. (*a*) Osteochondritis upper tibial epiphyses; (*b*) Sarcoma shaft right tibia. (2) Chronic low-grade infection. (3) Hodgkin's disease (Sir Thomas Fairbank). (4) Neurofibromatosis. (5) Myelomatosis. (6) Secondary to parathyroid tumour. (7) Melorheostosis.

14.11.56: Readmitted Queen Mary's Hospital for Children, Carshalton.

Blood count (16.11.56): Total W.B.C. 6,000. Neutrophils 59%, lymphocytes 32%, monocytes 8%, eosinophils 1%. Hæmoglobin 82% (12·1 grams %). E.S.R. 49 mm. in first hour.

Urine (15.11.56): Protein nil. Deposit: Amorphous phosphates.

Blood chemistry (16.11.56): Alkaline phosphatase 22 units. Calcium 11·6 mg./100 ml. Inorganic phosphorus 15 units. Zinc sulphate flocculation 15 units. Electrophoretic analysis of the serum shows a marked increase in gamma globulin. The calcium and phosphorus are also elevated. Marrow biopsy from ilium (15.11.56): No evidence of myelomatosis or neoplasm. Blood culture (15.11.56): No growth after three weeks' incubation. Right leg now one inch longer than left. Treated by three weeks' intensive penicillin.

11.12.56: E.S.R. 22 mm. in first hour.

17.12.56: Control X-ray (Fig. 4A, B) suggests consolidation of lesion of tibial shaft. Discharged home. Diagnosis still not known.

Rotational Dislocation of Atlas on Axis.—F. G. St. Clair Strange, F.R.C.S.

E. H., female, aged 21. Physical education student.

17.7.56: During a rag the patient fell and hurt her neck. Admitted with head held fully rotated to right. Pain and tenderness of upper cervical muscles. No neurological signs.

X-rays showed rotational dislocation of atlas on axis. No fracture seen.

Fig. 1.—X-ray showing lateral view of skull and atlas with almost exact antero-posterior view of axis and remainder of cervical spine. Both superior articular facets of the axis can be seen devoid of corresponding atlantal articulations.

Treatment: A gentle manipulation without anæsthetic, and head traction. 48 hours later: Plaster collar applied.

7.9.56: Plaster removed. Felt collar supplied.

5.10.56: Full range of movement present in neck.

Disorders of the Temporomandibular Joint.—J. L. HARRINGTON, L.R.C.P., M.R.C.S., L.D.S.

An analysis of the clinical aspects of 260 cases of disorders of the temporomandibular joint reveal that one or more of the following symptoms may be present: (1) Clicking (2) Locking, (3) Pain.

(1) *Clicking.*—This symptom when unaccompanied by locking or pain is of little significance and no treatment is usually necessary. It is often due to the anatomical shape of the glenoid fossa and eminentia articularis which allows an asynchronous movement of the head of the condyle with the meniscus. Self-inflicted trauma, such as yawning or biting hard food substances, will often produce this symptom which will become resolved in a few days with adequate rest of the joint. Should the patient complain of locking of the joint or pain, then attention must be given to faulty articulation of the teeth which is invariably present.

(2) *Locking.*—Limitation of movement may be severe and is often maximal on awakening; or slight when it may be accompanied by a swing of the mandible away from the affected joint on opening the mouth. This symptom is alleviated by correction of the dental abnormality.

(3) *Pain.*—Two types of pain can be differentiated: the one occurring in the region of the joint and accompanied by local tenderness, or referred to any branch of the trigeminal nerve, while the other type manifests itself as a deep dull ache in the facial musculature.

In the first type, the pain invariably occurs on the same side of the face to which the mandible moves on eccentric excursions. The essential factor is abnormal tooth contacts which cause deviation of the mandibular arch during its path of closure. Radiographically there may be no evidence of alteration or loss of joint space, but occasionally the condyle is forced posteriorly and there is then diminution of joint space between the condyle and the tympanic plate.

Pain, however, has no direct relationship to this malposition, but is probably due to the stretching or torsion of the lateral ligaments and capsule around the joint (*see* Fig. 1).

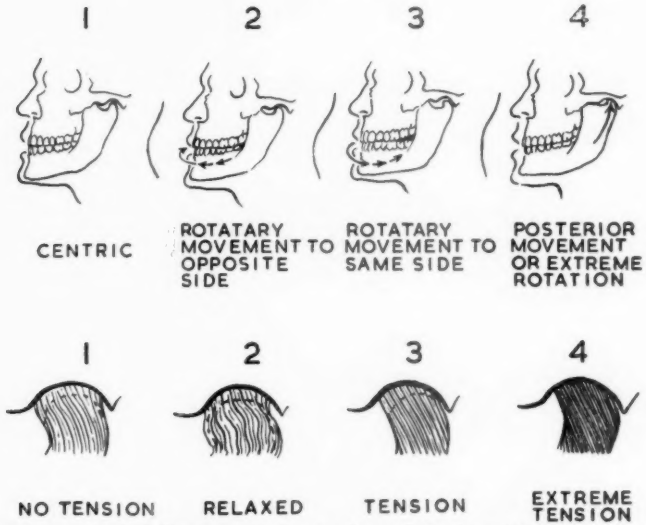

FIG. 1.—Diagrams 1, 2, 3 illustrate varying tensions of the lateral ligament of the mandible under normal masticating movements. Diagram 4 exhibits stress when abnormal dental contacts are present. Clinically tenderness can be palpated via the external auditory meatus or in the pre-auricular region.

Treatment consists in the correction of the dental abnormality, when the painful symptoms rapidly disappear.

In the second type, the patient complains of a dull deep muscular ache. When the pain is unilateral, the causative factor is usually abnormal tooth contacts. Not infrequently, however, there is loss of vertical height in occlusion due to loss of teeth or alveolar bone, when the pain is bilateral. This is noticeable in the masseter, digastric and anterior fibres of the temporalis, which muscles may also be tender to palpation (Fig. 2).

A B

FIG. 2.—A, A case of bilateral pain and tenderness in both masseter and digastric muscles due to loss of posterior teeth, resulting in the overclosure of the mandible. B, Establishment of oro-facial harmony by insertion of dental prosthesis with relief of symptoms.

Skeletal asymmetry may cause the mechanism of mastication to become inco-ordinated, and the line of occlusion may slope definitely from one side of the face to the other. This may produce similar signs and symptoms to those already described.

Whether as a result of a skeletal abnormality or an acquired fault in occlusion, the muscles of mastication are hyper-activated as a result of the patient endeavouring to maintain some kind of functional mastication. This muscle hyper-activity will often lead to muscle fatigue which is characterized by deep pain and tenderness in the muscles of mastication. In these cases, localized pain around the temporomandibular joint may not be present.

With this syndrome it has been found that the facial nerve may also be involved and, rarely, the muscles of facial expression may be affected with apparent facial nerve paresis. Electrical stimulation of the VII nerve, however, as it crosses the posterior border of the ascending ramus of the mandible, produces a greater excitation of these muscles compared with the normal side (in comparison with Bell's palsy where the response may be diminished or absent).

Correction of the dental disharmony reduces this increased excitation, relieves the pain, and within fourteen days of treatment both sides react equally to the same stimulus.

It is considered that the deep pain and tenderness are the result of muscle fatigue and not of muscle spasm since electromyographic records taken of these cases do not show increased frequencies to the point indicating spasm, e.g. 200 per second.

An explanation is at present impossible. There are definite links between all the branches of the facial nerve and corresponding branches of the trigeminal nerve, and the key to the involvement of both these nerves in the syndrome would appear to lie here. Whether these connexions contain fibres running from the facial to the trigeminal, vice versa or both ways, is unknown. One possible thought is that occasionally throbbing is complained of with a severe pain in the joint, and it may be that the basic cause is a vascular one fired off by impulses from the temporomandibular joint which is innervated not only by somatic fibres but by autonomic fibres also. Beyond this hypothesis it is not possible to go.

Arthrogryposis Multiplex Congenita.—R. H. SEWELL, Ch.M.

Male child, aged 2½ years, the elder of two children, the younger being normal. Both parents show no abnormality nor is there any family history of skeletal or muscular disease.

At birth, the deformities present were:

(1) Ulnar deviation and palmar flexion of the hands.

(2) Fixed extension deformities of the elbows and adduction deformities of both shoulders.

(3) There was a severe bilateral talipes equino-varus.

The feet have been corrected with difficulty by manipulations and strapping and later, Denis Browne splints. He walked at 18 months. Despite repeated manipulation and splinting, the elbows remain in full extension.

Opinions were sought on the future treatment of this child. The Meeting was of the

general opinion that no surgical treatment was advisable, at least at present, although cases of successful Clarke's transplant in older children with an adequate pectoralis major were quoted.

? Giant Cell Tumour of Neck of Radius.—R. H. V. HAFNER, F.R.C.S.

W. O., aged 64. Paper maker.

History.—Patient hurt his right elbow at work in April 1956. X-ray showed no bony injury but revealed a multilocular cystic tumour occupying the proximal end of the radius at the junction of the shaft and the neck (Fig. 1). The cyst was expanding the bone and contained small nuclei of bone. The differential diagnosis was thought to lie between the following: (1) Enchondroma. (2) Osteitis fibrosa cystica (localized). (3) Osteoclastoma.

The pain and stiffness of the elbow which had followed the injury rapidly subsided and within a few weeks the joint was clinically normal.

Check X-ray of the right elbow taken in July 1956 showed no change from the previous films (Fig. 2).

FIG. 1.—X-ray of elbow, postero-anterior view.

FIG. 2.—X-ray of elbow, lateral view.

The patient is doing a heavy job and is entirely free from symptoms.

The questions before the Meeting were: (*a*) Diagnosis. (*b*) Should the tumour be excised because of the possibility of malignant change?

Past history.—Nine years ago, the patient injured his right elbow and was said to have sustained a fracture of the head of the right radius. No records are available.

A medico-legal point has arisen in this case because of the possibility that this cystic tumour had resulted from the injury nine years ago.

POSTSCRIPT (March 1957).—Patient at work and symptom-free. X-ray appearances are unchanged.—R. H. V. H.

Result of Removal of Right Lunate Bone (Semilunar) Eighteen Years Ago.—W. E. TUCKER, F.R.C.S.

Male, aged 42.

February 1938: Injured right wrist playing hockey.

First seen on 1.4.38 with X-rays which showed dislocation of the lunate bone.

As attempts at manipulative reduction failed, an open operation was performed and the bone removed.

Since then has been playing county hockey, hammer throwing and weight lifting. Has full range of right wrist movement and only has an occasional twinge.

The following cases were also shown:

Sequelæ of a Fractured Head of Radius.—G. O. TIPPETT, F.R.C.S.

Non-union of Ulna.—J. H. MAYER, F.R.C.S.

(1) Case Illustrating Use of Walking Caliper in Plaster Boot: Fracture of lower third of the right tibia and fibula. **(2) Case Illustrating Use of Home-made Removable Walking Caliper:** Arthritis of the right knee-joint—unknown origin.—W. E. TUCKER, F.R.C.

Section of Proctology

President—RONALD W. RAVEN, O.B.E., T.D., F.R.C.S.

[*January* 9, 1957]

Carcinoma of Pelvic Colon. Secondary Deposit in Left Ureter Simulating a Primary Tumour. Left Hydronephrosis.—H. R. THOMPSON, F.R.C.S.

Mrs. E. S., aged 47.

23.3.55: *Laparotomy* for acute bowel obstruction due to growth at pelvi-rectal junction. Transverse colostomy.

1.4.55: *Sigmoidoscopy* and biopsy showed an infiltrating adenocarcinoma at 15 cm.

7.4.55: *Laparotomy.*—"Growth infiltrating the abdominal wall, uterus and small intestine, and was considered inoperable." Section of a hard nodule of tissue from the right broad ligament showed it to be adenocarcinoma.

10.7.56: Patient remained well until readmitted to hospital with abdominal pain and vomiting which responded to colostomy wash-outs; the pain, however, persisted.

22.8.56: First attended St. Mark's Hospital as a thin, dehydrated, ketotic woman with a gross small bowel obstruction. Hiccoughing following continuous vomiting for fourteen days.

Laparotomy.—Findings: (1) Obstruction due to matted coils of small intestine firmly adherent to growth in recto-sigmoid bowel. (2) No secondary deposits in the liver. (3) Solid tumours of right and left ovaries. (4) Rigid, distended appendix. (5) Left hydronephrosis with nodule in lumen of left ureter at pelvic brim.

Operative procedure: (1) Resection of pelvic colon and upper rectum with 4 ft. of adherent small intestine. (2) Pan-hysterectomy with appendages. (3) Left nephrectomy for left hydronephrosis and hydro-ureter secondary to ureteric growth at pelvic brim. (4) End-to-end colo-rectal anastomosis.

Stormy post-operative convalescence due to partial breakdown of anastomosis and pelvic abscess. Discharged eight weeks after operation.

27.11.56: Readmitted. Stricture at anastomosis dilated.

19.12.56: Intraperitoneal closure of colostomy.

Pathological report.—"(1) Ulcerating constricting adenocarcinoma of rectosigmoid. (2) Secondary deposits in both ovaries. (3) Secondary deposit in appendix. (4) The tumour in the ureter was a secondary deposit of adenocarcinoma. There was permeation by adenocarcinoma of a moderately sized vein close to the tumour in the ureter. There was obvious invasion of veins in sections of the primary growth."

Comment.—The case is of interest for: (1) the urological aspect; (2) the prognosis and operability; (3) the diagnosis.

(1) *Urological aspect.*—Most surgeons, on finding a left hydronephrosis and left hydroureter at operation for advanced carcinoma of the pelvic colon, would correctly assume this to be due to direct involvement of the ureter by the colon growth. This was the assumption in the case reported until it was found that the colon growth lifted easily off the ureter without dissection, revealing a hard nodule within the lumen of the ureter just below the pelvic brim. The nodule was about 2 cm. long and was apparently malignant tissue (Fig. 1). Was this an associated primary carcinoma

FIG. 1.—Hemisected left kidney and ureter seen from behind, showing ureteric tumour—a secondary deposit of colonic adenocarcinoma.

of the ureter, or a secondary deposit from the primary colon growth, and, if so, what was its mode of spread to the ureter?

Histological examination showed that the ureteric tumour was a deposit of colonic adenocarcinoma. From the ease of separation of the primary colon growth from the ureter and the appearance of the nodule and the ureter it is unlikely that the spread was by direct extension. A clue to the possible spread was provided by the finding of a peri-ureteric vein adjacent to the ureteric tumour filled with adenocarcinoma and it is suggested that the secondary deposit developed in the lumen of the ureter from retrograde venous spread.

Kontoff and Hershman (1954) reported a case of primary transitional cell carcinoma of the LEFT ureter being treated five months after a RIGHT hemicolectomy for carcinoma of the ascending colon. They stated that since Rayer (1841) in France first reported a case of primary carcinoma of the ureter, there have been 312 such cases reported but that none of these cases was associated with another primary malignancy.

The treatment of this urological complication arising during the resection of a carcinoma of the pelvic colon was a matter of expediency. As the right kidney and ureter were normal, it was considered that a left nephro-ureterectomy was preferable to reconstructive surgery as the operation had already lasted three and a half hours.

(2) *The prognosis and operability.*—I think it is agreed that fixity of a growth as assessed at clinical examination should not condemn a patient as inoperable. Everyone is familiar with the growth that appears hopelessly fixed, clinically, being quite easily removed at operation and most give their patients the benefit of a trial dissection. If this fails a colostomy should be performed and the case reviewed every three months. In larged fixed growths after a colostomy the patient usually enjoys a period of nine to twelve months of good health and during it the surgeon should elect to do a second laparotomy. Sometimes he will find that the case has become operable.

Dukes (1949) refers to the paradoxical situation that beyond a certain limit in size, the larger the tumour the less likelihood there is of metastases and, presumably, the better the prognosis.

Cooke (1956) discussed advanced carcinoma of the colon with emphasis on the inflammatory factor. He gave examples of 14 cases of extended resections for carcinoma of the colon where both the quality and length of life were improved and extended in patients who might have been left as inoperable.

(3) *The diagnosis.*—It is interesting that the patient was originally admitted to hospital in March 1955 suffering from an acute abdomen and diagnosed as appendicitis. Laparotomy, however, revealed a distended cæcum and a large bowel obstruction due to a constricting growth in the pelvic colon. A distended cæcum can simulate appendicitis, but seventeen months later the appendix was grossly pathological, it was removed, and on section its lumen was full of secondary adenocarcinoma.

"Weaver's Bottom" (Ischial Bursitis).—DAVID BAILEY, M.Chir., F.R.C.S. (for IAN TODD, M.S., F.R.C.S.).

History.—W. E. B., male, aged 70, attended St. Mark's Hospital in September 1956. In 1921 a right-sided ischial bursa was excised at St. George's Hospital. He had remained well until August 1956 when he noticed a swelling in the left ischial region and a sinus developed in the right-sided scar. Weaver's bottom was diagnosed and X-rays demonstrated rarefaction of both ischial tuberosities with considerable irregular new bone formation. By November 1956 the left-sided bursitis became acute; patient transferred to University College Hospital.

Examination.—Right ischial region: Scar of previous operation with discharging sinus and recurrence of bursa. Left ischial region: Acutely inflamed bursa 7 cm. in diameter.

Operation.—13.11.56: Left ischial bursa excised intact with ellipse of overlying skin. A hæmatoma formed; it was drained; healing was slow.

Specimen.—Ovoid cyst 7 × 5 × 4 cm.; wall thick (0·25–1 cm.) with polypoid projections into lumen, which was filled with sterile, gelatinous, yellow fluid. "Chronic bursitis—no evidence of tuberculosis".

Comment.—This condition is rare to-day and is usually attributed to trauma by prolonged sitting, &c. Rowing may have been an ætiological factor in this case.

Intussusception of Appendix Simulating a Carcinoma of the Cæcum.—FRANK FORTY, F.R.C.S.

M. B., female, aged 61.

History.—Attacks of lower right colicky abdominal pain for one month, latterly with vomiting. Bowels acted normally; once loose, contained altered blood.

On examination.—Mass in right iliac fossa, mobile, slightly tender but no guarding. Pre-operative diagnosis: Carcinoma of cæcum with subacute intestinal obstruction.

Operation.—Mass in cæcum; no enlarged lymph glands; no secondaries in liver. Right hemicolectomy. Uneventful recovery.

Report (Fig. 1): The specimen consists of the terminal 5 cm. of ileum, the cæcum, appendix and 21 cm. of colon. The appendix is intussuscepted into the cæcum, and is grossly thickened. Its lumen is almost obliterated with cheesy material, but no tumour is seen.

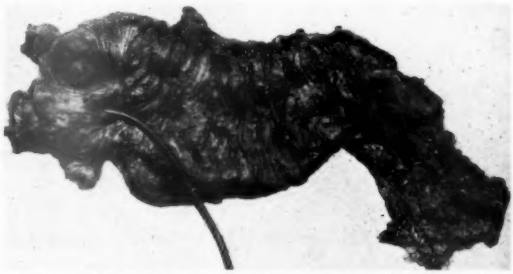

FIG. 1.—The operation specimen opened to show the intussuscepted appendix; ileo-cæcal valve shown by rubber tube.

Histology.—Section: No tumour, only the acute inflammatory changes associated with the intussusception, the muscle coats being particularly affected.

Comment.—About 100 cases of intussusception of the appendix have been reported (Fraser, K., 1943, *Brit. J. Surg.*, 31, 23).

Ætiology: Concretions, tumours, mucoceles, enlarged glands, worms, have been associated conditions. In many cases, as also in this case, no causative factor was found.

Symptomatology: Intussusception of the appendix occurs at all ages. It runs a chronic course extending over weeks or months. Severe colicky pain and a palpable mass in the right iliac fossa are constant findings. In a minority blood or mucus is passed *per rectum.* An X-ray after a barium enema generally reveals a filling defect in the cæcum. The usual diagnosis is acute appendicitis or carcinoma of the cæcum.

Treatment.—Appendicectomy with or without preliminary reduction of the intussusception, or hemicolectomy if a growth is suspected—or if the intussusception has become compound and includes cæcum, ileum or ascending colon.

Stenosed Segment of Descending Colon Associated with Trauma.—RUPERT CORBETT, M.Chir.

Specimen shown to the Section for diagnosis was the stenosed segment due to trauma or to an underlying condition such as regional colitis (Crohn's disease).

Male, aged 36—labourer.

17.3.56: Fell from height of 14 ft. and admitted as an emergency with abdominal pain, at 1 p.m. Had fracture of 8–9–10–11 left ribs and of left ilium. Abdominal pain persisted. At 6 p.m. glycerin suppositories gave a fæcal result; no blood in motion or in urine. Left-sided pain persisted. Condition satisfactory. During night passed blood *per rectum.* Blood pressure 90/60. Given pethidine—improved.

18.3.56: Much improved. Still blood *per rectum.* Urine clear.

22.3.56: Bleeding subsided. W.B.C. 21,000. Abdomen soft though tender on left side.

30.3.56: *After eight days* stools became offensive with pus. W.B.C. dropped to 6,000.

7.4.56: *One week later* improved; tender in left iliac fossa. Passed 2–3 motions daily.

21.4.56: *Five weeks after admission*: Anæmic; Hb 76%; transfused.

12.5.56: *Eight weeks after admission.* Discharged. Improved. Stools normal consistency though narrow and ribbon-like. Bowels open 2 to 4 times daily.

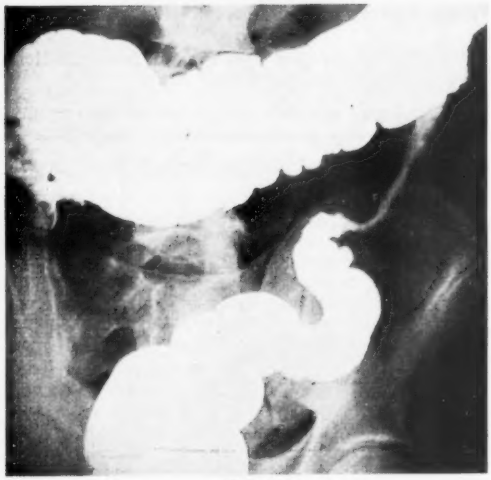

FIG. 1.

FIG. 2.

X-rays: Barium enema showed free passage as far as cæcum; descending colon was narrow (Fig. 1).

8.11.56: Readmitted for operation.

13.11.56: *Resection of descending colon* twelve weeks after injury. 12 in. of colon resected and end-to-end anastomosis. Specimen injected for blood supply (Fig. 2). Mid-colic and left colic arteries were tied. No rupture was detected.

29.11.56: Discharged.

21.12.56: X-rays—Bowel normal, five weeks after operation.

I am indebted to Mr. J. D. Griffiths for the injection of the sigmoid. He has been working on the subject of blood supply to the colon. The resected sigmoid did not reveal any arterial block or damage. I think that the condition could have been caused by trauma, although the interval between it and the established diagnosis was about eight weeks.

Pathological report (22.11.56).—*Macroscopic:* The specimen of colon is 29 cm. in length after fixation, with the attached meso-colon and omentum adherent. The vessels had been injected with opaque blue dye. The colon is shrunken, its lumen is reduced throughout and its wall thickened due partly to folding of the muscularis. The mucosa is abnormal, but the lining is so discoloured that it is impossible to say whether ulceration is present or not.

Histology: Sections of the colon showed inflammatory changes in all coats. The mucosa shows low-grade active chronic inflammation and there is evidence of extensive regeneration. No ulceration is apparent. The submucosa shows fibrosis and scarring—especially superficially where the fibres of the muscularis mucosæ are widely separated by fibrous tissue. There is fibrous thickening of the serous coat and occasional small groups of inflammatory cells in the outer part of the wall. In these sections there is no apparent abnormality of the vascular supply.

Seven lymph nodes from the meso-colon show only non-specific reactive changes.

The appearances are somewhat suggestive of Crohn's disease though proof of this is lacking.

In the discussion **Mr. R. V. Cooke** said he thought that the changes which had taken place could be explained by a very extensive traumatic thrombosis of the bowel wall, subsequent on a severe contusion. This is supported by the passage of blood and pus from the bowel. Subsequently fibrosis and narrowing of the lumen followed.

Potassium-secreting Tumour of the Colon.—CYRIL COOLING, F.R.C.S. and DAVID MARRACK, M.D.

This title was given to a large villous tumour of the sigmoid colon because of the vast secretion of potassium associated with the lesion, which led to a serious deficit in the body potassium.

A female, aged 35, attended the Gordon Hospital in 1947, complaining that she had been passing water through the rectum for five years but blood had been present only at the onset. The symptoms had started six months after a normal, but rapid, labour.

Every morning she passed a loose motion mixed with fluid followed by a formed stool, and for the rest of the day passed this watery fluid with every micturition.

Sigmoidoscopy and barium enema at that time failed to reveal any evidence of tumour or vesical fistula and the diagnosis was mild colitis. Medical treatment and colonic lavage provided some improvement. The symptoms did not unduly worry her.

In 1955 she attended the Gordon Hospital, and was admitted for investigation under Mr. S. O. Aylett. For a month she had felt ill with vomiting and abdominal discomfort, and for four days no fæcal matter had been passed. The rectal fluid continued to be poured out at 4–6 pints per day.

Examination revealed a heavily loaded colon but a rectum containing only fluid. The clinical impression was that she had subacute intestinal obstruction.

	m.eq./l.		mg./100 ml.
Serum		Serum	
sodium ..	120	calcium ..	10·3
potassium ..	2·2	Blood urea ..	97
chlorides ..	80		
HCO_3	27		

During the first six days intravenous electrolytes were given as follows:

	Pints
2N saline	12·5
N/5 saline and glucose ..	5
KCl (40 m.eq./l.) ..	8
M/6 sodium lactate ..	2

By mouth she received 144 grams of potassium citrate. It was found difficult to improve the serum electrolyte values in spite of this therapy. She complained of weakness and diplopia, and had episodes of tingling and numbness of the hands and occasional attacks of carpopedal spasms, a phenomenon which may occur during potassium replacement therapy with an existing low serum and total body potassium, yet a normal serum calcium (Fourman, 1954).

A barium enema examination revealed a fluffy outline in the distal part of a long sigmoid colon and sigmoidoscopy showed a granulomatous polypoid mass at 15 cm. A left hemicolectomy was performed for a palpable tumour of the sigmoid colon (Fig. 1). This

FIG. 1.—Macroscopic appearance of the villous tumour of the sigmoid colon removed by left hemicolectomy.

was examined by Dr. George Lumb who found an enormous encircling cauliflower tumour mass covering 11 cm. of colon but bounded by normal mucosa. Histological examination showed a papilliferous tumour with no evidence of malignancy but very active mucus-secreting goblet cells present.

Since removal of the tumour she is well and the serum electrolyte values have been normal.

Gabriel (1952) pointed out the difficulty of diagnosis of these soft impalpable, pale tumours but he considered that most of them would show some malignant change on serial section; a view endorsed by Swinton, Meissner and Soland (1955) who found such a change in 31·4% of their series at the Lahey Clinic. On these grounds it would appear that a radical approach in treatment is justified, a view expressed by Mr. Gabriel and giving excellent results.

In this case symptoms of electrolyte imbalance were present. It is known that severe fluid loss from the rectum as in gastro-enteritis may produce a similar condition, a phenomenon not previously recorded in association with villous tumours.

Electrolyte estimations of the simultaneously collected urine and rectal fluid on the third day after admission were:

	Urine m.eq./l.	Rectal fluid m.eq./l.
Sodium ..	0·5	122
Potassium ..	2·5	25

The significant facts are:

(1) The urine values approach the minimal possible level of both sodium and potassium which precludes potassium loss from other renal and steroid disorders.

(2) If the rectal fluid were a simple transudate the sodium/potassium ratio should be comparable to that of the serum.

(3) The tenfold increase in potassium over sodium values in this fluid can only be accounted for by selective reabsorption of sodium, urea, phosphate, chloride, calcium, phosphatases or by active secretion of potassium. It cannot be proved which occurred but as colonic mucosa is believed to secrete potassium under normal circumstances the vast increase in epithelial area in this tumour may account for this loss.

(4) Chronic loss of potassium presumably occurred over thirteen years. Signs and symptoms developed following one month of intermittent nausea and vomiting which probably reduced the potassium intake and further upset the intake/output balance of potassium.

(5) During potassium replacement therapy she developed tetany with full *main d'accoucheur* and Chvostek sign when the serum calcium and alkali reserve were normal. It was *not* relieved by calcium gluconate intravenously.

(6) All the serum electrolyte abnormalities corrected themselves and remained normal after removal of the secreting tumour.

Section of Dermatology

President—Louis Forman, M.D., F.R.C.P.

[*November* 15, 1956]

Tuberculous Glands with Skin Involvement.—S. P. Hall-Smith, M.D., M.R.C.P., and J. McMurray, M.D.

A. W., aged 72.

History.—Six months ago, following right-sided sore throat, he developed swelling of right pre-auricular region. Three months later the swelling discharged pus, and soon after the surrounding skin became inflamed and reddened. During the same period further glands around the angle of his jaw on the right side, adjacent neck and supraclavicular area were involved. Before being referred for dermatological advice it was thought that he was suffering from a pyococcal infection and he was treated with Aureomycin ointment and intramuscular penicillin.

Examination.—The right cheek was covered by a diffuse erythematous papulo-pustular eruption. Over the pre-auricular area there was a prominent raised, infiltrated swelling; three discrete, cystic reddened swellings ran round angle of jaw; these have pointed and discharged pus. A palpable chain of glands extended from the right ear to right supraclavicular region. A small punctate ulcer could be observed between the anterior and posterior faucial pillars on the right side.

Investigations (17.10.56).—Hb 16·1 grams% (109%). W.B.C. 11,000 (polys. 80%, lymphos. 12%, monos. 8%).

Film: Red cells, leucocytes and platelets all appeared normal.

E.S.R. (Wintrobe) 31 mm. in one hour. (Normal 0–9 mm.)

26.10.56: *Swab:* A few pus cells and Gram-positive cocci seen. The culture gave a small growth of *Staphylococcus aureus*, coagulase +ve. Sensitive to erythromycin and Chloromycetin; resistant to penicillin, Aureomycin, Terramycin and streptomycin. *Mantoux test*, 0·1 c.c. 1/10,000 tuberculin: Positive (moderate reaction).

X-ray chest (15.10.56): Both costophrenic sulci clear. The heart and mediastinal shadows were normal and the lung fields clear.

Beard hairs: No fungus or pathogenic yeast isolated.

Biopsy of skin of right cheek, 17.10.56 (Dr. J. McMurray): This showed chronic inflammatory reaction of tuberculous type. No acid-fast bacilli were seen. There was also a pyogenic inflammatory reaction. Culture of the skin lesions gave a pure growth of *Staphylococcus aureus* (coagulase +ve).

25.10.56: A lymph node in the upper right cervical group was removed. This showed a tuberculous reaction with acid-alcohol-fast bacilli in the lesions. There was moderate caseation. Appearances resembled those seen in primary lymph gland tuberculosis in children. Some weeks later a culture of pus from fluctuant swelling below the skin lesion gave a growth of tubercle bacilli. It is not possible, at the moment, to say whether this is a human or bovine type.

Comment.—The findings are consistent with a primary tuberculous complex arising from the right tonsil involving the right upper cervical lymph nodes. The explanation for the skin lesion may lie in the probable lymph blockage with retrograde extension upwards from the infected lymph nodes. The localized skin œdema may have rendered atypical the appearances of the skin tuberculosis and also increased the possibility of secondary infection by *Staphylococcus aureus*.

Other possibilities, however, could be a primary senile tuberculosis either of right tonsil with lymphatic gland involvement and spread upwards and downwards, or of right lung with spread to hilum up the right paratracheal lymph glands and to involvement of right cervical group. This point may be clarified by subsequent investigation.

Dr. C. D. Calnan: I think the important thing in this case is the glands. The man is 72 and Rich (1951), in his book on tuberculosis, mentions this senile variety of tubercle in which the symptoms, signs, and the clinical course are different. Resistance to the organism changes in old age. I have seen a similar problem in an elderly patient with a big mass of glands at the neck, believed to be carcinomatous. At autopsy the mass was found to be tuberculous and, in addition, she showed other findings of senile tuberculosis with involvement of unusual organs such as the spleen.

REFERENCE

RICH, A. R. (1951) The Pathogenesis of Tuberculosis. 2nd Edn. Oxford.

POSTSCRIPT.—Two weeks after the patient was shown at the meeting (29.11.56) he developed pyrexia, consolidation and probable collapse of the lower lobe of the left lung. It was thought by a consultant chest physician that he had active tuberculous glands in the mediastinum, one of which had ulcerated into his left lower lobe bronchus. It was suggested that if this gland was situated behind the left auricle, it would not be seen on X-ray and would also explain the patient's sudden development of auricular fibrillation. The patient's general medical and skin condition has improved with streptomycin, PAS and isoniazid. At present he is reluctant to be admitted to hospital for further investigation.—S. P. H.-S.

Acanthosis Nigricans.—P. J. HARE, M.D., M.R.C.P.

Married woman aged 42.

Gynæcological history.—1938: Toxæmia of pregnancy. Posterior occipital presentation, necessitating manual rotation and forceps delivery. 1943: Consulted gynæcologist for vaginal discharge: cervical erosion cauterized. 1950: Mild prolapse observed but cervix reported normal then and in 1954. 1956: Induration of cervix detected in August; cervical biopsy showed anaplastic carcinoma and radium was applied. Cervical lesion estimated at not more than one year's duration.

Dermatological history.—1942: Onset of discoloration of the skin of the sides of the neck and elbow folds. 1947: Seen by Dr. I. Martin-Scott who suggested a differential diagnosis of acanthosis nigricans or pseudoxanthoma elasticum. At that time the clinical changes consisted of tiny pigmented papules varying in colour from sand to deep brown, running in lines between the normal skin furrows of the axillæ, elbow folds and the sides of the neck. There was no atrophy or telangiectasia. Mouth and vulva normal. Biopsy showed a lymphocytic infiltrate in the dermis, with pigmented melanophores and colloid blocks, forming tiny papules with a thinned epidermis. Dr. W. Freudenthal stated that the histological features excluded the diagnoses suggested and that atrophic lichen planus seemed probable. At some time the likelihood of poikiloderma atrophicans vasculare must have been suggested and the case was shown with this diagnosis at the International Congress of Physicians in 1947.

1956: The patient thinks that the skin condition remained unchanged until a few months before entering hospital for the radium treatment. Pigmentation then increased and spread to parts previously unaffected. At that time she felt well apart from backache and a vaginal discharge: she was not suffering from fatigue, loss of weight or abdominal symptoms. She is now going downhill rapidly.

Examination.—The skin of the exposed parts is slightly dusky and both surfaces of the hands and fingers are horny. The palms show scattered pigmented spots but the palmar creases are not pigmented. In the axillæ and umbilicus there are slightly warty slate-coloured patches. The sides of the neck and the folds of the elbows are pigmented. The vulva is brownish-black and is crowded with closely set papules and warty growths. A few of the latter are scattered irregularly on the face, trunk and limbs. The roof of the mouth shows leukokeratosis. No pigmentation of the oral mucosa.

Investigations.—Plasma electrolytes normal. 17-ketosteroid excretion 6·8 mg./twenty-four hours (normal). Blood pressure 140/86. Biopsy from skin of pubis (8.11.56): Consistent with acanthosis nigricans.

Discussion.—There is histological evidence that she had poikiloderma in 1947, but, with the exception of pigmentation, no changes characteristic of this disorder have appeared. If she genuinely had poikiloderma, is there any significant connexion with the later development of acanthosis nigricans?

Dr. R. M. B. MacKenna: She shows very well typical changes on the palms, a matter which most of the literature does not emphasize. It seems to me that when in doubt as regards lesions in the armpits, if in the early stages one can find a velvety thickening of the palms, which proceeds to the stage shown in this patient, it is a very considerable aid to diagnosis. I do not think this change happens in all cases of acanthosis nigricans but when it occurs diagnosis is facilitated.

Necrobiosis Lipoidica.—P. J. HARE, M.D., M.R.C.P.

Married woman aged 43.

Family history.—No diabetes mellitus.

Past history.—Bronchiectasis since childhood. Lobectomy in 1949. Cough persists.

History.—Skin lesions for two years. Tender red nodules have appeared on the thighs and shins. These become flattened and painless after some months. Varicose veins for years but no phlebitis.

Examination.—Obese. B.P. 110/70. All peripheral pulses present and of good volume. Fundi normal. Varicose veins in both legs. No œdema or induration.

On both shins there are confluent areas of redness with yellowish centres and a glazed telangiectatic surface. On the left shin there is also a more discrete area 4 cm. in diameter with the same general appearance but with a distinctly raised narrow border. On the left thigh there is a slightly raised tender red area about 3 cm. in diameter.

Investigations.—Urine: no reducing substances. Fasting blood sugar and glucose tolerance test normal. Blood cholesterol 269 mg./100 ml. Mantoux test positive 1 : 1,000, negative 1 : 10,000.

Plethysmography (legs): high resting rate of blood flow and normal response to ischæmia.

X-rays.—Limbs: no calcification of blood vessels. Chest: changes corresponding to results of right lower lobectomy. Lung fields otherwise normal.

Biopsies.—(1) From a recent lesion: perivascular accumulations of histiocytes, epithelioid cells, giant cells of Langhans and foreign-body type, plasma cells and lymphocytes. No necrobiosis of connective tissue. Vessels normal.

(2) From an old lesion: the same inflammatory changes to a lesser degree and with fewer giant cells. In addition there are large areas of necrobiosis with early fatty change: there is fibrosis and occlusion of small arteries.

Two lesions have been treated by injecting hydrocortisone suspension into them, with cosmetic improvement.

The case is shown because it suggests that the early stage of necrobiosis lipoidica is inflammatory and not necrobiotic. Miescher's "granulomatosis disciformis" may in some instances represent this histological stage. Another point is the presence in the same patient of two types of mature lesion which have been thought characteristic of necrobiosis lipoidica in the diabetic and non-diabetic respectively.

The following cases were also shown:

Chronic Œdema of Hand—For Diagnosis.—Dr. W. D. FLETCHER and Dr. A. JARRETT.

Tuberculoid Leprosy.—Dr. W. H. JOPLING (for Sir GEORGE MCROBERT).

Recurrent Non-scarring Granuloma of Face for Diagnosis.—Dr. C. H. WHITTLE, Dr. A. J. ROOK, Dr. J. L. MOFFATT and Dr. R. A. DAVIS.

Kerato-acanthoma of the Lower Lip (Red Margin).—Dr. C. H. WHITTLE and Dr. R. A. DAVIS.

Pemphigoid.—Dr. M. WITHAM (for Dr. W. N. GOLDSMITH).

Dermatitis Herpetiformis.—Dr. W. FRAIN-BELL (for Dr. R. T. BRAIN).

(1) **Norwegian Scabies.** (2) **Familial Macular Pigmentation and Nerve Deafness in (a) Mother and Small Child, and (b) Unrelated Adult Male.** (3) **Acne Conglobata.**—Dr. I. MARTIN-SCOTT.

Ectopic Cutaneous Schistosomiasis.—Dr. H. HABER and Dr. J. COWLEY.

Ichthyosiform Erythroderma (Brocq).—Dr. H. WILSON and Dr. H. HABER.

Disseminated Granuloma Annulare.—Dr. PETER SMITH.

A paper on **Chronic Liver Disease as a Cause of Pruritus** was read by Dr. J. R. K. PREEDY.

[*December* 20, 1956]

Melanosis.—D. I. WILLIAMS, F.R.C.P.

B. G., aged 29. Occupation—shorthand typist.

History.—In February 1954 she noticed brown patches on the forehead and cheeks. Since this time these have spread slightly on to the neck and *pale* areas have appeared within the brown patches. The condition becomes more obvious during the summer months and less noticeable in the winter. She has never taken arsenic in any form or used any preparations containing silver or mercury. She has continued to use her face powder and cream without any noticeable effect on the pigmentation.

Past history.—No previous skin trouble. Asthma in 1949—none recently.

Examination.—Scattered over the forehead, cheeks, and upper parts of the neck there are areas of macular pigmentation, showing both a diffuse and follicular pattern. Intermingled with these pigmented patches are a number of rounded pale areas.

Investigations (right side of neck).—The section shows numerous chromatophores in the superficial layers of the corium carrying considerable amounts of melanin. There is a slight increase of pigment in the basal layers of the epidermis.

Treatment.—(1) 15–30% monobenzyl ether of hydroquinone in emulsifying ointment for one year, but little or no benefit, unless the pale areas interspersed in the pigment are due to the drug. (2) Ardena sun screen.

Comment.—This patient shows a slightly unusual picture on the face of a diffuse and follicular pigmentation, present for two years. About a year ago white areas appeared in the pigmentation and have remained very much the same. The pigmentation is quite unchanged except for the white areas since I first saw her.

I have no idea of the ætiology and I do not know what one would call this apart from melanosis. There is no mercury or silver in the section. We have not done patch tests with the cosmetics; she has continued to use the same cosmetics for the last two years.

POSTSCRIPT (January 1957).—Patch tests with cosmetics with and without exposure to sunlight were negative at forty-eight hours and there was no pigmentation after fourteen days.

Dr. I. B. Sneddon: I do not think Dr. Williams has excluded the possibility of cosmetics; I would have stopped her using cosmetic creams for a year. She can continue to use powder but I think it is the scent in the creams which causes this and it will take a year to fade.

Dr. C. D. Calnan: This case is similar to one shown to me by Dr. P. D. Samman at St. John's Hospital. When patch-tested she gave an eczematous patch to the face cream but only produced melanosis on the face.

Dr. H. Haber: I think the condition will stay a long time no matter what you do. The pigment lies within chromatophores and I cannot see how it can be removed by external remedies. It will take, I think, two to three years before any appreciable change will take place.

Dr. I. Martin-Scott: I think it is important that she should avoid *all* contact with scent. In a case of mine with deeper pigmentation involving the lower face and anterior aspect of the neck, the deep brown colour disappeared in eighteen months, when the woman ceased to use scented soap, powder and creams.

Dr. J. R. Simpson: Is 15% to 30% of the monobenzyl ether of hydroquinone used usually? I have found even 2·5% will produce a dermatitis.

Dr. H. Wilson: The worst case I have ever seen was a woman who demonstrated beauty creams; her face became so bad that the firm no longer employed her. The rash gradually got better after she changed her job, but I think it took two years.

Dr. F. Ray Bettley: Perhaps I could mention a woman whom I had in my ward because of this condition. She was using a well-known face-cream of a pinkish colour, containing eosin and some sort of safranine. When a patch test was done it gave negative results but it showed a sensitivity to ultra-violet light. I did the same patch test on the remaining 9 patients in the ward, and 8 out of 10 showed that this cream had the effect of producing a temporary light sensitivity in the test area.

Dr. Williams: I do not think this is the cosmetic type of pigmentation; the colour and the marked follicular reaction make me feel that it is different. I shall do patch tests, and shall tell her not to use make-up.

Tuberculoid Leprosy.—E. N. M. JOHNSTON, M.B., M.R.C.P. (for H. J. WALLACE, M.D., F.R.C.P.)

D. B., male, aged 20. Student. Siamese.

History.—In November 1955 this patient noticed numbness and an eruption involving the skin of the outer side of the right ankle. He was seen by Dr. G. Hodgson, who found an anæsthetic granulomatous lesion associated with thickening of the right lateral popliteal nerve. A biopsy showed a chronic inflammatory reaction in the dermis, mainly localized around the vessels and skin appendages, composed of lymphocytes and vacuolated reticulum cells. No acid-fast bacilli were seen.

Lepromin test strongly positive. *Chest X-ray*—no evidence of lung lesion.

Treatment.—A course of dapsone was started in April this year. The dose has been gradually increased to 700 mg. weekly. There has been steady improvement. A roughly triangular area of slightly scaling hypopigmented skin with peripheral superficial dilated vessels remains.

Dimorphous Leprosy.—E. N. M. JOHNSTON, M.B., M.R.C.P. (for H. J. WALLACE, M.D., F.R.C.P.).

N. H., male, aged 15. Anglo-Indian.

History.—This boy has been in this country for three years. He previously resided in Madras. Three months ago he noticed a non-irritating rash on his legs with numbness of the right thigh. The rash has since spread to the arms, face and trunk. Nasal discharge has been present for ten years.

Examination.—Skin: A symmetrical eruption of bluish-red oval macules and plaques of various sizes are present on the above sites. The edges of many lesions are ill-defined. Patches of hypopigmentation with anæsthesia are present in some of the above macules, but not all lesions are anæsthetic. *Peripheral nerves:* No significant enlargement. *Chest X-ray:* The lung fields appear clear. *Skin smear:* Positive for acid-fast bacilli resembling *M. lepræ*. *Nasal scraping:* No acid-fast bacilli. *Histology:* Changes of lepromatous leprosy with many acid-fast bacilli are present. *Lepromin test* negative.

Dr. W. H. Jopling: I would like to thank Dr. Wallace for asking me to say a few words about these patients. The first has a single lesion on one ankle which shows definite sensory loss, and, in addition, the common peroneal nerve is thickened. Such findings are pathognomonic of tuberculoid leprosy. The fact that no acid-fast bacilli can be demonstrated is of no importance for the diagnosis is made from clinical and histological evidence together with a strongly positive lepromin reaction.

The second patient is more difficult to classify. At first sight one might diagnose lepromatous leprosy but I would place him in the borderline (dimorphous) group as some of the lesions are atypical in appearance and have sensory loss. His positive skin smears, negative nasal scraping and negative lepromin reaction are all in keeping with borderline leprosy. These patients have an unstable immunity and if untreated they tend to progress to the lepromatous type. A few remain borderline or develop features of the tuberculoid type. My impression is that this patient will progress to the lepromatous type and it is therefore important to commence treatment soon.

With sulphone therapy the first patient will be cured within a matter of eighteen months but the second patient will require at least three years of treatment before skin smears become free from bacilli and it will be necessary to continue on a maintenance dose after that for at least five years, if not for life. This patient's dosage of sulphone must be increased cautiously in the early stages for treatment in borderline leprosy is liable to precipitate a type of "reaction" characterized by swelling and redness of the lesions associated with rapidly developing neural damage.

Atrophie Blanche.—R. H. MARTEN, B.M., M.R.C.P. (for SYDNEY THOMSON, M.D., F.R.C.P.).

J. L., male, aged 70. Retired.

History.—He has suffered from chilblains on the hands, feet and ears every winter since childhood. In recent years they have tended to break down and ulcerate but have caused him little or no pain. For the past five to six years he has noticed marked Raynaud phenomena and last winter he developed gangrene of the left little finger and left second toe. The patient thinks that some of the scarring on the hands and feet has occurred at the sites of ulcerated chilblains. He has never suffered from intermittent claudication or chest pain, although in recent years he has become breathless on exertion. He has never had any X-ray treatment.

Past history.—Red blotches on the palms as long as he can remember. Ten to eleven years ago an ulcer on the right heel treated by skin grafting. One year ago developed "blisters" on the left heel.

Family history.—Several members of his family have suffered from chilblains.

Examination.—On the backs of his fingers there are areas of atrophie blanche of varying sizes and shapes. In addition one or two of the lesions show small adherent keratoses. The skin over the terminal parts of the fingers is somewhat bound down but there is no true acrosclerosis. The palms of both hands are mottled and red and the left little finger shows loss of the distal two phalanges. On the dorsal aspects of the toes, feet and around the ankles there are similar patches of atrophie blanche. In addition, both feet show scattered dilated venules but no varicose veins; pitting œdema and some keratotic thickening over pressure points. Around the right ankle the skin is slightly pigmented while a small patch of dry gangrene is present on the left fourth toe. All the pulses in the lower limbs can be felt except the right dorsalis pedis which is absent. Blood pressure 210/110; no signs of heart failure. The nervous system is normal although the soles of both feet are hypersensitive to touch and sweating is more marked on the right side.

Investigations.—Hæmoglobin 98%; E.S.R. 25 mm. in the first hour (Wintrobe); blood urea 21 mg.%; blood W.R. negative; liver function tests normal; plasma proteins 6·45, albumin 4·65, globulin 1·8 grams %; no cryoglobulins found. Urine normal. Chest X-ray: Aortic arch is slightly wide but the heart shows no appreciable enlargement. X-ray of hands: No abnormality except deformity of the left little finger. No calcification or erosion seen.

Treatment.—Priscol 25 mg. three times a day to 50 mg. four times a day with some subjective improvement.

The following cases were also shown:

(1) **Lyrle's Disease.** (2) **Case for Diagnosis: Long-standing Dermatitis Clinically Like Pemphigus Foliaceous.**—Dr. D. I. WILLIAMS.

Syringocystadenoma.—Dr. R. H. MARTEN (for Dr. D. I. WILLIAMS).

Blue Nævus.—Dr. R. H. MARTEN (for Dr. SYDNEY THOMSON).

Mac o-ulcus Perstans (Castellani).—Dr. E. LIPMAN COHEN.

[*December* 6, 1956]

DISCUSSION ON THE EARLY MANAGEMENT OF SUBARACHNOID HÆMORRHAGE

Dr. J. MacDonald Holmes (Staffordshire General Infirmary and Midland Centre for Neurosurgery):

My contribution is to present the experience and conclusions of a general physician in a provincial non-teaching hospital concerning what I prefer to call spontaneous intracranial hæmorrhage, as subarachnoid hæmorrhage is commonly accompanied by intracerebral bleeding and the distinction between the two is an arbitrary one.

Spontaneous intracranial hæmorrhage is one of the most common and most rapidly lethal neurological emergencies encountered in the medical wards of a general hospital and it is generally acknowledged that the mortality in cases managed conservatively is in the region of 50%–60%. It is difficult to obtain accurate figures of the number of cases occurring annually in this country, but a reasonable estimate is probably between 4,000 and 5,000. At present only a small proportion of these are seen in the early and most dangerous stage of their illness by neurologists and neurosurgeons.

I am convinced that surgery in suitable cases is the only treatment which has much to offer in reducing the high mortality of conservative management, which is indicated in Table I, compiled from reviews in recent literature.

It would be impossible for neurosurgeons to assess, let alone treat, more than a small fraction of the cases which are admitted every day to the hospitals of this country. Ideally, all cases should be admitted to neurosurgical units, but it is improbable that this will be attainable on a nation-wide scale for some time to come. Surgery undertaken as an emergency measure for intracranial hæmorrhage necessarily carries a high mortality. This cannot fairly be compared with that of comparatively safe elective surgery undertaken during the phase of recovery, which has given rise to unduly encouraging mortality figures. This has led many people to say that conservative treatment is preferable at all stages of the illness, but I do not hold this view and would like to have the support of a neurosurgeon's opinion in all cases during the acute phase. This is not always available and it is therefore all the more

TABLE I.—MORTALITY RATES OF SUBARACHNOID HÆMORRHAGE AS GIVEN IN REVIEWS OF CASES TREATED CONSERVATIVELY

TABLE II. — INTERVAL BEFORE DEATH FROM LATE RECURRENCE IN THE PRESENT SERIES

8 of the 57 survivors of the initial illness died of recurrences during the fifteen-year period of follow-up. This gives a total mortality of 51% and a mortality from recurrences in the survivors of 14%.

Period in years	Number of cases
Less than one year	1
1–2	2
2–3	1, after a fourth recurrence
3–4	2, one after a third recurrence
4–5	1
11	1

important that general physicians, and particularly those in hospitals without a neurosurgical department, should have a knowledge of the essential methods of management and investigation of these cases, and be able to select those which are suitable for surgical treatment.

I have based my own views in the first place on a series of 100 consecutive cases seen during the fifteen years 1936–1951 and followed up during that period. I have excluded, perhaps wrongly, all cases of rapid or sudden death in elderly hypertensive or arteriosclerotic patients. The distinction between primary intracerebral hæmorrhage and subarachnoid hæmorrhage is clinically difficult and often artificial, but I was concerned more with the results of conservative management than the incidence of causes of bleeding.

By conservative management I mean rest in bed for at least one month, with good nursing care and all that it implies; attention to the bowels, bladder and skin, the prevention of dehydration, the judicious use of sedatives, antibiotics and sulphonamides, and cautious lumbar puncture to relieve headache.

This uniformity of management has not produced any remarkable lowering of the mortality in my cases during the initial stages of the illness, when compared with other published series shown in Table I, but the mortality from late recurrence is lower than that given in most reviews.

Tables II, III, IV, V and VI analyse briefly the data obtained from the 100 cases:

TABLE III.—DURATION OF FOLLOW-UP OF 57 SURVIVORS OF INITIAL HÆMORRHAGE

Period in years	Number of cases
1–2	15
2–3	10
3–4	5
4–5	5
5–6	7

1–2 weeks.. ..	15	12
2–6 weeks.. ..	6	6

TABLE V.—LESIONS FOUND AT NECROPSY IN 35 CASES

Anterior cerebral and anterior communicating aneurysms ..	10
Internal carotid aneurysms	2
Middle cerebral aneurysms	12
Posterior communicating aneurysms	4
Intracerebral hæmorrhage, no aneurysm found	4
Angiomatous malformations, one cerebellar, one parietal ..	2
Subacute bacterial endocarditis with multiple miliary aneurysms and intracerebral hæmorrhage..	1

In one case polycystic kidneys and a large aneurysm of the abdominal aorta were found. Six small aneurysms were found on the right middle cerebral artery.

In one case there were two aneurysms in the left middle cerebral distribution, one of which had ruptured.

Large intracerebral clots were found in 12 cases, but some clot formation was present in all the cases examined at necropsy.

TABLE VI.—FACTORS INFLUENCING THE PROGNOSIS IN 100 CASES TREATED CONSERVATIVELY

	43 fatal cases	57 survivors
Arterial hypertension (B.P. over 160 mm. systolic) ..	16	11
Coma at onset	24	9
Recurrence of bleeding during period in hospital ..	22	4
Previous history suggesting subarachnoid hæmorrhage	2	0

20 of the survivors had permanent neurological disabilities and of these 2 died within a year of further hæmorrhage. 4 patients were completely disabled by hemiplegia. 3 patients were completely disabled by dementia. All the other survivors were able to work to some extent. 4 were dysphasic, 3 had a III nerve palsy, 2 had a VI nerve palsy, 2 had a visual field defect and 2 were epileptic.

Since 1951, I have collected a further consecutive series of 79 patients, but up to now few of these have been followed up, so I do not know how many have died of recurrent hæmorrhage after leaving hospital. Some of these patients have been treated conservatively as before, some have been treated with hypotensive drugs in addition, whether hypertension was present or not, and some have been treated by surgical measures. Angiography has been used as a diagnostic aid in 37, or nearly half of these cases, and is absolutely essential if surgical treatment is to be considered. There has been much controversy as to whether angiography should be done in the early stages of the illness because of the risk of aggravating arterial spasm, but I am not convinced that the risk is a great one. If the condition of the patient is desperate I prefer to perform angiography soon after admission to hospital if it seems that on general clinical grounds surgery will be possible.

Table VII gives a brief analysis of this later group of 79 cases.

TABLE VII

Total number of cases	79
Total deaths during period in hospital	25
Mortality for all cases	31·6%
Cases treated surgically	17, with 4 deaths
Surgical mortality	23·5%
Cases treated with hypotensive drugs	30, with 9 deaths
Mortality in group treated with hypotensive drugs	30%
Cases treated conservatively as before	32, with 12 deaths
Mortality in group treated conservatively ..	37·5%
Angiography performed	37
Angiography failed	2

I have classified my 100 cases into four broad groups.

Group 1 includes fatal cases in which there is a rapid development of mid-brain or medullary compression from massive intracranial hæmorrhage, causing death in less than twenty-four hours. Treatment of any kind is useless in this type of case, of which there were 14 in the group of 43 fatal cases.

Group 2 includes cases in which there is a slower development of brain-stem compression, with gradually increasing stupor and neurological signs. In this group death occurs in from two to three days up to a fortnight after the onset, and there may or may not be clear-cut evidence of recurrent hæmorrhage. This type of case is the most important in which to consider surgical treatment and I think all should be investigated by angiography with the minimum of delay. There were 23 cases of this type in the 43 fatal cases. Also included in this group are those cases in which the symptoms simulate those of a cerebral tumour or abscess rather than hæmorrhage; there is no very abrupt onset and the changes in the cerebrospinal fluid may be equivocal and may not at first suggest that bleeding has taken place. There were three examples of this "pseudotumour" syndrome in the series.

Group 3 includes cases in which there is an interval of recovery from the initial hæmorrhage, followed by a fatal recurrence during the period in hospital. This happened in 6 cases of the 43 and it is probable that surgery undertaken in the quiescent period would save some of these cases.

Group 4 includes cases of undoubted hæmorrhage without loss of consciousness or only transient loss at the onset, progressing to complete recovery, or left with some neurological disability. There were only 8 deaths from late recurrent bleeding in the 57 survivors in this group and I think that surgery need not be considered when some months have elapsed since the acute stage.

It is in Groups 3 and 4 that decision between surgery and conservative management is most difficult. Generalization is impossible and the decision must be made on the individual case after careful assessment in consultation with the surgeon, and this must include bilateral carotid angiography with carotid compression on the side of the lesion, when one is found,

to determine the adequacy of the collateral circulation through the circle of Willis. When bleeding does recur at an early stage there is no doubt that surgery should be undertaken whenever possible.

To summarize, surgery should be considered at an early stage in the management of spontaneous intracranial hæmorrhage with the exception of patients who are moribund when admitted to hospital, or whose general physical condition or age makes them unfit for operation. The need for surgery will be the most urgent in those cases I have included in Group 2, with gradually increasing intracranial pressure due to large intracerebral clots or early recurrence of bleeding. The need for surgery is less insistent in those who are recovering, but again becomes urgent if bleeding recurs. My personal experience has not so far enabled me to decide whether elective surgery in recovered cases is of greater value than conservative treatment.

I would like to mention very briefly one case, clearly falling into Group 2, in which an emergency operation certainly saved the patient's life, and considering the site and nature of the lesion, produced a result which was satisfying beyond all expectations.

The patient was a woman aged 38, a physiotherapist, whom I saw on 8.12.55. She had had two very slight attacks of subarachnoid bleeding during the previous five weeks and five days before had a further severe hæmorrhage with the development of an almost complete left hemiplegia. She was semi-stuporous with occasional Cheyne-Stokes respiration. Bilateral papilloedema was present. She was transferred to the Midland Centre for Neurosurgery and a right carotid angiogram showed a loculated middle cerebral aneurysm arising from the region of the first branch of the right middle cerebral artery. Displacement of the vessels suggested the presence of a large intratemporal hæmatoma. An exploratory craniotomy was done the same evening by Mr. R. C. Connolly, who aspirated 80–100 c.c. of clot from the right temporal lobe. The aneurysm was seen to arise from the main stem of the middle cerebral artery and was so extremely thin-walled, that it was excised together with the portion of middle cerebral artery from which it arose. After a stormy convalescence this patient made an extremely good recovery, with hardly any trace of left hemiplegia. Her only disability is a left homonymous hemianopia, but this has not prevented her from being appointed as a director of physiotherapy. Post-operative angiograms show that the right middle cerebral artery is completely interrupted shortly above its origin.

Dr. R. A. Henson (Neurological Department of The London Hospital and Maida Vale Hospital for Nervous Diseases):

Subarachnoid bleeding is a frequent concomitant of apoplexy, either as a result of extension of intraventricular hæmorrhage, or, more rarely, from direct rupture into the subarachnoid space. Such cases of primary cerebral hæmorrhage have been excluded from consideration in this communication. This is in some ways illogical as I have included a number of cases of cerebral angioma and tumour in my series, and in a few of these the hæmorrhage was primarily intracerebral or intraventricular: however, it is clearly necessary to include vascular hamartomas in the discussion, while the clinical picture in the tumours was apparently that of subarachnoid hæmorrhage, and this must explain my inconsistency. Secondly, this is not a discussion on the treatment of cerebral aneurysms and angiomas: the cause of bleeding is unknown in about one-half of my cases.

The diagnosis of subarachnoid hæmorrhage rarely causes difficulty: it is less easy to be certain that the bleeding is not originally intraventricular in some patients. The collection of the cerebrospinal fluid specimens in three separate tubes is a useful routine for the exclusion of the traumatic tap. It is sometimes difficult to decide just when the hæmorrhage has occurred and how many bleeds there have been in any one patient. Complaints of headache are often made over a period of some days before the obvious hæmorrhage occurs, and these episodes may indicate minor degrees of bleeding. Similarly there may be difficulty in diagnosing recurrences when the patient is in hospital, particularly in the comatose patient. In my experience minor degrees of hæmorrhage are uncommon in patients with demonstrable aneurysms. Small bleeds may be due to cerebral angioma, neoplasm or even blood dyscrasia, but more frequently they occur in patients in whom investigation reveals no cause for the bleeding. Small repeated bleeds are again rather characteristic of angiomas, and they also complicate the course of various neoplasms. Croft and I have recently drawn attention to the need for recognizing those patients in whom the subarachnoid hæmorrhage is spinal in

origin (Henson and Croft, 1956). The onset with sudden pain in the back is easily discerned, providing that early intracranial extension has not provoked cerebral disturbances, including impairment or loss of consciousness.

Table I shows the causes of subarachnoid hæmorrhage in an unselected series of 137

patients seen at Whipps Cross Hospital, and in 100 selected patients admitted to The London Hospital under the care of Sir Russell Brain or myself. There is no doubt that congenital cerebral aneurysm is the commonest cause. The diagnosis of aneurysm has to be made on probabilities as a rule; characteristic localizing signs are comparatively rare in an unselected group. Age is no barrier to the diagnosis. Post-mortem studies were done on 13 patients dying over the age of 70, at Whipps Cross Hospital, and in 8 of these the cause was a congenital aneurysm. Table II shows the age scatter at the time of the first hæmorrhage in patients with proven angiomas or aneurysms. There were 46 patients with hypertension, the diastolic pressure being 100 mm. of Hg or more, in the unselected series, and 26 died. Post-mortem examinations were carried out in 22 of these cases and revealed congenital aneurysms in 16. The disparity in the number of angiomas in the two series is probably accounted for by case selection and different age scatter. In the series of 15 angiomas seen at The London Hospital the clinical picture was sufficiently clear to allow of pre-angiographic diagnosis in all save one. There were 4 examples of spinal subarachnoid hæmorrhage in The London group and 1 in the Whipps Cross series, a total of 5 in 219 cases.

Diagnosis includes both discovery of the cause of bleeding and evaluation of the factors operating in the production of symptoms in an individual case. These factors include subarachnoid, intracerebral and intraventricular hæmorrhage, intracranial hypertension and its sequelæ, subdural hæmatoma and vascular spasm. The role of the blood pressure may also be important, whilst the development of atheroma in or adjacent to an aneurysm plays a part in determining the time of the bleed. The assessment of these factors in any one case may be virtuallv impossible, frequently several will be acting. In the moderate case of subarachnoid hæmorrhage with a brief period of altered consciousness and no focal signs, it is generally safe to assume that the important factors are the blood in the subarachnoid space and some degree of intracranial hypertension. Even in more severe cases, where the patient is comatose, recovery may occasionally take place without symptoms of cerebral damage, and here these same two factors plus vascular spasm may form the pathological mechanisms. In the comatose patient, however, intracerebral bleeding, usually with intraventricular extension, is the common finding. The importance of the intracerebral clot alone in the course of the disease does not appear to be great from my material. In all save 1 of the 15 cases of the series studied *post mortem* at The London Hospital the intracerebral hæmorrhage was associated with intraventricular bleeding. Subdural hæmatomata are not infrequently found at necropsy, usually with associated intraventricular and cerebral bleeding; no such lesions have been demonstrated by angiography in our cases. Vascular spasm is undoubtedly important. I had one patient who died with extensive cerebral infarcts which were presumably due to this mechanism. The differentiation of the focal disturbances due to intracerebral hæmorrhage from those of vascular spasm may be impossible both clinically and by angiography. Brain-stem hæmorrhages secondary to hypertension may cause death, the intracranial hypertension being produced by intracranial hæmorrhage or by the aneurysm itself acting as a space-occupying lesion. To summarize, the important factors are the hæmorrhage itself, subarachnoid, intracerebral and intraventricular, vascular spasm and intracranial hypertension. In severe cases all these mechanisms are usually operating.

Attempts to treat such patients by ventricular puncture, evacuation of intracerebral clot or decompression have been undertaken in only a few cases, for my surgical colleagues have not been anxious to interfere. When these methods have been used the results have been unhappy except in one patient whose intracerebral clot was evacuated with apparent benefit.

The difficulty of assessing the results of treatment of subarachnoid hæmorrhage is notorious. The mortality in patients treated medically appears to be in the region of 50%. I have not been able to discover a series of cases which have been offered the benefits of neurosurgical treatment which can be fairly compared with an unselected series treated medically. Patients admitted to neurological or neurosurgical departments have frequently survived the dangers of the first few hours or days; they are among the younger sufferers and serious concomitant disease is more commonly absent than in an unselected group. Neurological and neurosurgical series contain a relatively large number of patients with angiomas. My own material reflects these difficulties. I have a consecutive series of 137 patients admitted to Whipps Cross Hospital between the years 1950 and 1956. This series is unselected. The patients were persons whose affairs determined that they were in the region of the hospital when they were stricken; they were nearly all admitted at an early stage of the illness, many within hours and the vast majority within two days. On the other hand I have the series of 100 consecutive patients who were under the care of Sir Russell Brain and myself at The London Hospital between 1948 and 1956. This is a highly selected group. 43 patients were admitted as emergencies from the surrounding area or the neurological clinics, 12 were seen in private practice, but 45 were transferred from other hospitals. This source has latterly dried up as patients are usually referred to neurosurgeons. Generally speaking, patients were admitted much later in the course of the illness. 18 cases are common to both series. I have seen about 130 of the 219 cases in the acute stage. The two groups are in no way comparable. The age scatter shows a remarkable dissimilarity (Tables III and IV). The figures for The London cases are in line with those quoted by physicians from teaching hospitals. The Whipps Cross age scatter is more in accordance with that recorded by previous reporters of large unselected series. 35% were over 60. There is also a marked difference in the mortality, 27% in The London series and 49% for the Whipps Cross group: and yet 52 of the patients admitted to Whipps Cross were transferred to The London or Maida Vale Hospitals for investigation and possible neurosurgical treatment. This high mortality is accounted for by the number of cases admitted in a moribund state. 18 died within twenty-four hours, 35 within a week, and 45 within a fortnight of onset of bleeding. There was only one cerebral angioma in the series. Many of The London cases were admitted after the early period of danger was past, and there was a comparatively large number of angiomas.

In my unselected group of patients a clear policy of management has been gradually evolved, and it is of this series that I wish to speak. The follow-up is 100% to two months after the hæmorrhage and 87% to date. It was my original intention that surgical treatment should be provided for all patients who might conceivably benefit from it. Here I would like to thank my colleagues who have co-operated with me. Originally some heroic measures were adopted. Several seriously ill younger patients were transferred within a matter of one to two days: we gave up this policy for the simple reason that they all died, usually before angiography could be carried out. On the other hand we soon recognized, as have most other workers, that the danger period of recurrences in patients with aneurysms is maximal from the fifth or sixth to the fourteenth day, so recently we have aimed to transfer patients about the end of the first week, provided that age, associated disease and general condition do not contra-indicate this measure. We soon came to feel that if the patient could not weather the storm of the first bleed there was little to be gained by transfer. 52 patients were actually transferred. Table V shows the reasons for retaining the remaining patients and treating them medically. There were 85 in this group, of whom 49 died (58%). The mortality in the patients transferred was 37%. The difference is purely a reflection of the general condition of the patients and severity of the bleeding in the medically treated group. It does not seem to be the result of treatment by surgery. Many patients were clearly unsuitable for neurosurgical treatment on the score of age. About a quarter died in the first bleed, and one-half of these within twenty-four hours. The middle-aged and elderly patients frequently had serious associated disorders, obesity, severe hypertension, coronary disease, carcinomata, serious pulmonary affections; in fact the whole gamut of internal disease is covered in this group. Post-mortem examinations on patients who died do not suggest there were any major errors in judgment. There were 9 patients who were theoretically suitable for investigation but who were not transferred. Two refused, the other 7 were not seen by me, and it is rather ironical that all these 9 survived the initial bleed and were well at least two months later. 44 patients out of 52 transferred had angiograms. The missing 8 either died too soon or I changed my mind about the right course of management at a later stage in the illness. Table VI shows the results of angiography in both series. 14 of the 16 patients with negative angiograms survived; 1 died from carcinomatosis, which was

the cause of his hæmorrhage, the other had a further and fatal bleed, unfortunately there was no necropsy. Thus approximately one-third had negative angiograms and the consequent good prognosis which others have observed. Vertebral angiograms were only performed when specially indicated. In 1 patient angiography may have hastened death. 2 patients collapsed during angiography and the procedure was abandoned. Both recovered.

My surgical colleagues have co-operated closely in the treatment of these patients in the unselected group. They were invited to see the patients at an early stage and were sometimes warned of the impending arrival of cases of subarachnoid hæmorrhage. Table VII shows the various definitive surgical treatments carried out. The variety of these procedures, the differing times after hæmorrhage at which they were performed, and the small number of patients who came to surgery make it impossible to assess the value of any particular operation. The results of the operations in survivors are shown in Table VIII. Both patients

with internal carotid-posterior communicating aneurysms were left with partial III nerve palsies but were otherwise well on discharge. I have already commented on the results of measures to relieve intracranial hypertension or to evacuate intracerebral hæmatomata. The striking feature of these surgical figures is that they are so small. Out of 137 cases of subarachnoid hæmorrhage 52 were transferred for investigation; only 17 eventually underwent definitive operations for the causal lesion, and only 14 of these had aneurysms. This surely means that a vast amount of clinical material has to be combed to find a large series of surgically treatable aneurysms. I think it is also clear that in spite of a great deal of work by many people, the mortality from subarachnoid hæmorrhage in this particular series has only been slightly influenced for the better.

From this review of my own experience of an unselected series of patients with subarachnoid hæmorrhage I would suggest the following general lines of management. Firstly, the diagnosis must be established and an attempt made to define the cause on clinical evidence. There is probably little to be gained by transferring seriously ill patients as neurosurgical emergencies; they should be allowed to take their chance of weathering the first bleed. An exception should be made in those patients who develop symptoms of increasing intracranial hypertension without further bleeding, but these cases may be difficult to detect, and they are uncommon. If a patient survives his first bleed a decision must then be made whether to proceed to angiography, which would usually mean transfer to a special centre. The decision should be made within the first week so that the radiological examination may be carried out before the period of main danger of recurrence. In reaching this decision, age, general condition and the presence of associated illnesses should be considered. If there are symptoms or signs pointing to a diagnosis of aneurysm or angioma, angiography is called for unless other factors contra-indicate this course. Patients under the age of 40 should be investigated unless there are clear reasons for not doing so. With older patients each case should be decided on its own merits, and the decision should be made by a physician after a general appraisal of the case. Patients over the age of 55 are usually unsuitable for investigation with a view to surgery, but there are exceptions. A more conservative approach than this would be unwise until the value of hypothermia and advances in surgical technique have been evaluated.

Medical treatment consists of nursing care, maintenance of adequate airway, regulation of fluid balance, and the use of sedatives and analgesics. Meadows (1951) has discussed the important aspects of medical management. Hypothermia might prove helpful and is worthy of trial. Hypotensive drugs are probably best avoided, except in selected patients with established hypertension, and even then should be used with caution. It is my personal feeling that if we treat our next hundred unselected patients in conservative fashion, we shall show an immediate mortality and morbidity little higher than that of a comparable group in which all modern forms of diagnostic aid and surgical treatment are employed.

I wish to acknowledge the help of my colleagues, both clinicians and pathologists, in making their notes available to me.

Mr. J. M. Small (Neurosurgeon—The Midland Centre for Neurosurgery and the United Birmingham Hospitals): The basis of my experience of intracranial hæmorrhage rests on some 158 cases which were admitted to hospital under my care. All these cases had a definite diagnosis of hæmorrhage and the series does not include apoplectic seizures in the elderly arteriosclerotic. Of these 158 with undoubted hæmorrhage 4 had some condition such as glioblastoma, secondary deposit or spinal lesion. The pattern of the disease in all these gave evidence that they were outside the usual groups. The 154 cases remaining fall roughly into four large groups (Table I). About half of these patients were treated surgically,

TABLE I

but the other half were refused surgical treatment for various reasons of age, arterial hypertension, multiplicity of aneurysms, the position and nature of the vascular anomaly, or because no cause could be found for the bleeding.

When we exclude the group which succumb in the first twenty-four hours, we are left with a group who are clearly dying—often with bilateral spasticity, deep unconsciousness and evidence of hypothalamic and vital centre failure. Angiography and tentative surgery are useless here. Others are in varying stages of drowsiness or unconsciousness with a variety of neurological signs.

The results of lumbar puncture are not always clear-cut and easy to interpret. The bleeding may be into the brain substance or the subarachnoid space and it may give that curious result of a polymorphonuclear or lymphocytic reaction in the cerebrospinal fluid. I have seen several patients who have had a diagnosis of brain abscess made under these conditions before coming for neurosurgical investigation. Rigidity of the neck and Kernig's sign may be absent and lead to confusion. This is true not only of those who are deeply unconscious.

As the hours go by the development of an intracranial compressive lesion becomes obvious. Although pupillary abnormality may occur at the outset the development of a dilating pupil is of great importance, declaring the onset of tentorial coning. In my cases 33% of those operated upon had intracranial clots and of these 26 patients 23 survive. Therefore, one of the important surgical principles is the evacuation of sizable clot with the treatment of the causative lesion at the same time.

With developing neurological signs and evidence of intracranial compression, angiography will be needed before surgical treatment can be undertaken. There may, however, be a marked spasm of the arteries in the vicinity of an aneurysmal hæmorrhage, which itself may be quite small, and this spasm leads to ischæmia and neurological signs, sometimes in the periphery of this blood supply and at a considerable distance from the source of the bleeding. It may also lead to areas of infarction and œdema. Angiography may suggest that a clot is present, but all that is found is a bulky area of brain due to œdema. Decompression may be of some use in such cases. There may also be structural changes in the walls of the arteries impeding blood flow, giving a beaded appearance on angiography. I would say that surgical treatment of an aneurysm at this stage is fraught with danger, and I can see no value in its application unless there is a sizable clot requiring treatment. The management of a patient in a period of cerebral ischæmia can undoubtedly be helped by hypothermia. Cooling by ice-packs reduces the oxygen requirements of the ischæmic areas of brain. In the seriously ill patient without a clot this treatment may carry him to a stage when full investigation and treatment may be undertaken.

This vascular spasm seems to last five or six days. We know there are relatively few deaths from recurrent bleeding in the first week, so that my view would be that elective angiography should be performed at about one week after hæmorrhage. Should this be applied universally to all cases of hæmorrhage? We will consider this later. My series contained only a few who had but one hæmorrhage and made a full recovery.

Of my 26 cases with compressive intracranial clots 2 have been subdural and the rest intracerebral. Only 2 have been in the frontal lobe, due to anterior cerebral aneurysms, the rest in the temporal or parietal area. Temporal lobe clots, usually arising from a middle cerebral aneurysmal hæmorrhage, are extremely dangerous because of the high incidence of tentorial coning. This may persist in spite of evacuation of the clot and treatment of the causative lesion, even when the intracranial pressure is low because the uncus becomes impacted between the tentorium and the mid-brain. Since experiencing this condition I have always divided the tentorium to release the uncal impaction. This is imperative, for

if the tentorial cone persists in spite of low intracranial pressure death is inevitable, and elevation of the temporal lobe in an attempt to free the uncus is not enough.

The clot can safely be removed as the bleeding point has always been in the wall of the clot cavity, and never centrally placed in the clot. The clot also seems to have some predilection for a certain position in the temporal lobe, in particular it forms in a paraventricular position running along the side of the temporal horn as though there were some cleavage plane in this position which decides the course of the blood extravasation. In nearly half of my cases no angiographic cause of the intracerebral clot was demonstrated, but at operation an aneurysm was sometimes found or a tiny angiomatous area existing in the cortex, and there is no doubt that these tiny angiomata can cause very considerable intracerebral bleeding.

Some patients become drowsy without advance in neurological signs or evidence of compression, and suffer some upset in their fluid and and crystalloid balance and a low blood pressure. I have attributed this condition to pituitary infarction, and it is not surprising that aneurysms in the parasellar region should bring these problems in their wake, and the use of ACTH or cortisone in this group of patients is of the greatest value.

I am still not sure whether elective angiographic investigation should be performed under general or local anæsthesia. I think that in skilled hands general anæsthesia is preferable, and guards the patient from upset in the examination. Percutaneous angiography should be performed first on the affected side and followed by an angiogram on the opposite side. The angiogram may fail to reveal a tiny aneurysm or one occluded by clot, nor does the absence of a demonstrable lesion prove that there is no danger of fatal hæmorrhage in the future.

To have a full arterial picture a vertebral angiogram should be performed as well but I do not use this investigation without specific indications. Although aneurysms occurring in the posterior fossa can have surgical importance, they have been only of post-mortem interest in this series.

In my series there have been no deaths in the 21 cases of angioma which form 14% of the entire group, either in the 15 operated upon, or in the 6 in whom no surgery was undertaken. Hæmorrhages for which no cause can be found angiographically, 20% of this series, have had an equally satisfactory result. The 12 patients operated upon were all for large intracerebral clots—11 survived; and in the 20 who bled—some of them on more than one occasion—in whom no surgery was necessary, all have survived but one.

For 200 years surgeons have been interested in the treatment of aneurysms, and the principles of treatment are clear: the Hunterian principle of proximal ligation; the exclusion of the aneurysmal sac by the method of Matas; and the total removal of the aneurysm and its feeding vessels. It is on the basis of these principles and their effectiveness applied to intracranial aneurysms that surgical treatment must be considered.

Proximal ligation of the carotid artery is certainly not indicated in the acute stage with the vascular spasm at its height. Its only value can lie in aneurysms directly related to the carotid artery and its bifurcation. In this series 18 patients have had carotid ligation for such an aneurysm—some of them the common carotid alone, others the internal, or both—with 1 death and 1 hemiplegia, but there have been 2 late recurrent fatal hæmorrhages from the carotid aneurysm after two or three years.

The aim should be to obliterate *the aneurysm and its neck* from the circulation. Some aneurysms lend themselves to opening and packing with muscle; whilst in certain positions of the circle of Willis, particularly the anterior cerebral, proximal occlusion of this artery would appear to be of considerable value as it forms a cul-de-sac with probable thrombosis including the artery and the aneurysm. Wrapping the artery over its outer surface with muscle or cotton has been followed by recurrences in my hands, and some of these have been within twelve hours of this procedure.

In patients who are making a satisfactory recovery without residual disability, and have had but one hæmorrhage, the likelihood of a recurrence is considerable; the anxiety of recurrence in the minds of many of these patients is enormous. Angiography at the end of the first week after hæmorrhage should be undertaken in the majority of these people to determine the position of the aneurysm, to give some prognosis and to decide whether surgical treatment is advisable. An aneurysm on the back of the carotid artery on the non-dominant side, or on the posterior communicating, can usually be treated simply, safely and soundly. One on the middle cerebral artery of the dominant hemisphere would be an entirely different problem in a perfectly well patient—a fear of dysphasia from surgical procedure should halt the surgeon's hand. So we might pursue the position of the varying vascular anomalies to decide their safety for surgery. We still do not have all the information we require to determine the necessity for treatment in varying positions, and this alone is sufficient justification for investigation of these patients.

The value of a dry field by temporary vascular occlusion in the cooled patient is already improving the surgery of direct attack, with a higher percentage of good results.

DISCUSSION ON THE MANAGEMENT OF THE GANGRENOUS FOOT

Professor C. G. Rob (St. Mary's Hospital, London):

Gangrene of the toes and feet may be due to arrest of the arterial or of the venous flow, the latter accounting for less than 1% of cases. I shall describe those methods of treatment which aim at restoring the circulation to a gangrenous limb, because it is surprising how minimal the tissue loss may be after a successful procedure carried out by these newer methods.

Cause.—In most patients the cause of the gangrene is atherosclerosis and Table I lists the causes of gangrene of the toes and feet in 145 patients who have been under the care of the Surgical Unit at St. Mary's Hospital since 1950.

TABLE I.—CAUSES OF GANGRENE OF THE LOWER LIMBS OF 145 PATIENTS (18 BILATERAL)

Atherosclerosis	125	
Main vessel occlusions		90
Small vessel occlusions		11
Main and small vessel occlusions		24
Thromboangiitis obliterans	12	
Embolus	6	
Infective gangrene in a diabetic	4	
Venous gangrene	3	
Arterial injury	3	
Dissecting aneurysm. Thrombosed aneurysm. Raynaud's phenomenon	2	each
Polyarteritis nodosa. Neonatal. Congenital arterio-venous fistula.		
Radiotherapy	1	each

Treatment.—This includes control of diabetes and infection, stopping patients smoking (at least those with Buerger's disease), maintenance of normal blood pressure and hæmoglobin level particularly in patients with an acute arterial occlusion, and the treatment of any other general disease. The management of the gangrenous foot itself may be conservative or operative, but it is important to stress that the plan of conservative management outlined here should be adopted routinely before and after operation in those patients who are treated surgically.

CONSERVATIVE MEASURES

Reduction of the metabolic needs of the part.
Relief of pain.
Development of the collateral circulation.
Anticoagulants.
Maintenance of the patient's general health particularly the hæmoglobin level.
Prevention of infection.
Prevention of deformity.

The limb should be placed at rest flat in bed and on no account elevated, but short periods of dependency may be permitted. It should be kept cool and the patient as a whole heated to produce reflex vasodilatation. Sleep should be encouraged by relief of pain; alcohol is effective in many patients for this and assists vasodilatation. All splints and dressings

should be loose. Lumbar sympathetic nerve block may help. Infection should be prevented with local and systemic antibiotics. Anticoagulants are of value in many patients, and in our view they need not be stopped for surgical procedures, should these become necessary, because, if heparin is used and hæmorrhage appears to be excessive, protamine sulphate works as an efficient antidote in a few minutes. We have not had trouble from hæmorrhage during operations when patients have been taking the other anticoagulants under proper control.

Surgical Treatment

Sympathectomy.
An arterial reconstruction operation.
Amputation.

Every patient with a gangrenous foot should have an arteriogram if his general health is satisfactory and if there is evidence that the cause of the gangrene is occlusion of a main artery. Evidence of occlusion can be obtained by feeling the arterial pulses in the limb; if the femoral pulse is absent then it is good news because the patient will have an aortic or iliac occlusion and an arterial reconstruction operation should be successful; a palpable femoral but absent popliteal pulse means that an arterial reconstruction operation is still a possibility, but the presence of either ankle pulse with gangrene rules out a large vessel occlusion. An arteriogram serves to localize the occlusion and enables the surgeon to plan his operation.

Arterial reconstruction.—This is the treatment of choice. It has changed our whole approach to the gangrenous limb and such statements as "when the gangrene has spread to the dorsum of the foot an above-knee amputation is necessary" now belong to surgical history. The artery may be reconstructed in a variety of ways but, in general, the best results follow thromboendarterectomy, if the vessel is large, or the by-pass homologous arterial transplant inserted in the manner recommended by Cockett. Fig. 2 shows a good lesion for an arterial reconstruction; an occlusion of a large vessel with a reasonably satisfactory arterial lumen above and below the occlusion. Figs. 1 and 3 show the right foot of this patient, who was aged 52, before and six months after a successful thromboendarterectomy; only local tissue loss has occurred whilst without an arterial reconstruction procedure an above-knee amputation would have been necessary.

Fig. 1.—The foot of a dental surgeon aged 52. He has had a lumbar sympathectomy and an amputation of the great toe. The progress of his disease had not been arrested. Severe rest pain persisted.

Fig. 2.—The arteriogram from the patient shown in Fig. 1. He has a localized occlusion of the popliteal artery. An arterial reconstruction operation (thromboendarterectomy) was successful.

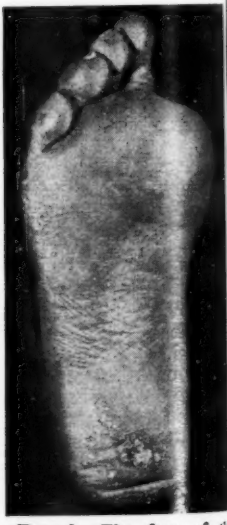

Fig. 3.—The foot of the patient shown in Figs. 1 and 2. He is back at work.

Table II shows that we have found it possible to perform an arterial reconstruction

operation on 30 or 20·6% of our patients with gangrene seen during the last five years and that 20 of these have been successful. A review of the patients included in Table II makes it apparent that, with the knowledge we have to-day, a greater number of these limbs could be saved. In our view about 25% of patients with gangrene of the toes or feet due to arterial disease can have their limb saved by an arterial reconstruction operation. This will mean a large number of unnecessary arteriograms but the number of limbs saved will justify the trouble.

The *selection of patients* with gangrene for arterial reconstruction depends to a greater extent upon the state of the arteries as shown on the arteriogram than upon any other factor. Because the alternative is a major amputation one need not be deterred by coronary artery disease or evidence of advanced generalized atherosclerosis. If the patient is fit enough for a major amputation he is fit enough for an arterial reconstruction operation. The essential feature on the arteriogram is an adequate artery distal to the occlusion; not only is the size of the vessel important but also the state of the vessel wall. While the best results will follow in patients with aortic or iliac occlusions, in exceptional circumstances a good flow may be re-established when the occlusion has spread as far down the limb as the bifurcation of the popliteal artery. A patient aged 36 had thromboangiitis obliterans; he had previously lost his other leg below the knee but had not stopped smoking, and he had advanced gangrene of his only foot and ankle and an above-knee amputation appeared to be needed. At operation a by-pass autogenous vein graft was inserted from the lower femoral artery to the posterior tibial artery which has worked well. In such a patient little harm is done even by an unsuccessful operation because the arterial reconstruction procedure is performed on that part of the patient which would otherwise have been amputated.

Type of arterial reconstruction operation.—In patients with gangrene the best procedure is a thromboendarterectomy (9 of our 30 patients had this type of operation). This is because a mild wound infection is by no means uncommon when there is an infected gangrenous lesion of the foot, and such infection causes little trouble when no foreign material has been inserted but may cause secondary hæmorrhage from, or thrombosis of, a homologous arterial transplant. When it is not possible to perform a thromboendarterectomy, a by-pass procedure using either a homologous arterial transplant or an autogenous vein graft gives good results, but we have to date found plastic prostheses unsatisfactory if one end has to pass below the inguinal ligament, although we find these materials satisfactory for the reconstruction of the aorta or iliac arteries.

Post-operative management.—Firstly, long-term anticoagulants should be given to every patient who has had an arterial reconstruction operation for thrombosis of an atheromatous artery. He should take them, if possible, for the remainder of his life. This is of particular importance in patients who had gangrene. We use phenylindanedione (Dindevan) for this purpose and consider that we may by this means reduce the incidence of recurrent thrombosis in the reconstructed arterial segment and of fresh thromboses in other arteries.

Secondly, the management of the apparently gangrenous parts: if the arterial reconstruction procedure restores palpable pulsation in the arterial tree distal to the occlusion, then at least six weeks should be allowed to pass before any form of amputation is undertaken. With a conservative approach of this kind it is surprising how apparently gangrenous tissues can recover with the line of demarcation forming well distal to where it was originally expected to be. The reason for this is that gangrene of the skin extends farther in the superficial than the deep layers; therefore after an efficient arterial reconstruction operation the deeper layers recover and when the dead superficial layers have peeled off a sound layer of

skin will be present underneath. The foot often remains swollen and œdematous for some months and an elastic bandage should be worn during this time.

Sympathectomy.—This is a most useful procedure, but it is important that the level of ganglionectomy should be such that the collateral circulation around an arterial block and the skin at the level of an amputation should be denervated. The skin of the lower limb is deprived of its sympathetic nerve supply as far as the supracondylar level of the femur by removal of the 2nd and 3rd lumbar ganglia. Inclusion of the first lumbar ganglion raises the level of skin denervation to the groin and if the whole buttock area is to be denervated the ganglionectomy should extend to the level of at least the 10th dorsal ganglion.

This means that a ganglionectomy designed to assist the healing of a mid-thigh amputation must include the 1st lumbar ganglion. If the lower ganglia only are removed the area of skin denervation will be entirely within the amputated portion of the patient. Similarly, if the arterial occlusion is in the lower aorta or iliac arteries the ganglionectomy should be from the 3rd lumbar to the 10th dorsal level at least, so that the lumbar and gluteal collaterals around the occlusion will be denervated.

Amputations.—We believe that conservative amputations should be used as often as possible; first the toes, next transmetatarsal, very occasionally a Syme, sometimes below-knee, occasionally Stokes-Gritti, and then the above-knee or mid-thigh amputation. In addition, in diabetic patients with infective gangrene a purely local operation removing all dead tissue but following no set plan is the treatment of choice. On 4 occasions in diabetics we have obtained primary healing after removal of one or more toes, the corresponding metatarsals and adjacent soft parts.

The transmetatarsal is a particularly valuable operation when the circulation is good enough for primary healing to take place. As will be seen, we have used this procedure on 7 occasions. This operation has the great advantage that an artificial limb is not needed. The Syme amputation is only occasionally satisfactory in patients with arterial disease; our 2 patients had palpable ankle pulses but gangrene of the dorsum of the foot where the flaps of a transmetatarsal amputation would have been placed and the Syme amputation healed well. The below-knee amputation is probably the most difficult, requiring a meticulous technique and two-layer closure if primary healing is to occur. We have had little experience of the Stokes-Gritti procedure which is favoured by some. The above-knee amputation has the advantage that healing is certain.

Venous gangrene.—This is a rare lesion. We have seen 3 cases in the last five years. One was in a girl of 13 who had ulcerative colitis and both the others were in patients with advanced intra-abdominal cancer. The cause is thrombophlebitis of the ileofemoral vein and the gangrene is due to thrombosis of the small vessels in the area of the gangrene, or to severe arteriolar spasm. Treatment is by elevation and anticoagulants, amputation being delayed until it becomes inevitable.

SUMMARY

(1) The treatment of choice of a gangrenous limb is to restore the circulation with an arterial reconstruction operation. This was carried out successfully in 20 or 13·7% of our 145 patients with gangrenous toes and feet and the tissue loss was small.

(2) When this is not possible sympathectomy may help but an amputation is often necessary. The level of sympathetic denervation should be planned to fit each individual patient.

(3) Amputations. The transmetatarsal gives very good results when the circulation is sufficient for healing. In diabetic patients with infective gangrene a purely local excision of dead tissue will suffice.

(4) After an arterial reconstruction operation for a lesion of this type the patient should take anticoagulants for the rest of his life.

ACKNOWLEDGMENTS

I wish to thank Mr. H. H. G. Eastcott and Mr. Kenneth Owen who performed many of the operations referred to in this paper and the other members of the Surgical Unit at St. Mary's Hospital for their help with the management of these patients.

Dr. Wilfrid Oakley (King's College Hospital, London) first discussed the relationship between diabetes and peripheral arterial disease, and brought forward figures in support of the argument that the latter was more closely related to old age than to the duration or severity of the diabetes. The high incidence of foot lesions in the diabetic could in large measure be accounted for by the coincidence of neuropathy, arteriosclerosis and sepsis.

The frequency of purely neuropathic conditions affecting the lower limbs, and especially the feet, in diabetics had not in the past been appreciated, and a number of slides showing

typical examples of perforating ulcers, localized gangrene, Charcot joints and a characteristic dorsal dislocation of the toes was shown.

Lesions of the feet in diabetes could be subdivided into four types: Septic, neuropathic, ischæmic and combinations of these three. Septic lesions should be treated in the same way in the diabetic as in the non-diabetic; neuropathic lesions responded well to local surgery while ischæmic lesions or those complicated by this factor often required more radical surgery. In such cases local surgery only succeeded when skin cover could be obtained without tension, and it was unwise to close the wound with sutures. When amputation was necessary it should be carried out below the knee by the Silbert technique.

Lastly, Dr. Oakley (Oakley *et al.*, 1956) described a method for protecting the heels in cases with ischæmia of the feet; this consisted of suspending the lower limbs in canvas slings by means of long springs connected to a beam above the bed. Since the introduction of this device, no trouble had been encountered with ulceration or gangrene of the heels in diabetic patients at King's College Hospital.

Mr. G. E. Mavor (Royal Infirmary, Aberdeen):

I wish to concentrate on atherosclerosis, particularly as it affects the arteries distal to the inguinal ligament. Firstly, I would like to take a step back from the picture of established gangrene, and consider the events which immediately precede it. Secondly, I shall consider the use of the by-pass arterial graft and mention some of the technical points involved.

It is now recognized that the onset and spread of secondary thrombosis in the arterial tree, particularly above the knee, follows a distinct pattern (Mavor, 1956*b*). Initially thrombosis is limited, the collateral circulation being adequate to meet the resting needs of the limb. However, the thrombus propagates in the main vessel and failure of the collateral circulation with involvement of the lower leg vessels by thrombosis results in gangrene.

FIG. 1.—Main vessel thrombosis which has been halted by the branches of the mid-portion of the popliteal artery. The distal segment of the popliteal artery is free of branches and healthy.

The failure of the collateral circulation is heralded by rest pain, the affected foot being discoloured, hyperæsthetic and cold. At this stage the main vessel is extensively thrombosed, the proximal limit of the thrombosis being the origin of the profunda femoris artery. This is the stage of femoro-popliteal thrombosis. In many of these patients, thrombus propagation distally may be temporarily halted by a cluster of small arteries about mid-popliteal level, the terminal inch or two of the popliteal artery remaining patent (Fig. 1). This segment of vessel is below knee-joint level, free of branches, usually healthy and easily accessible. Its existence makes the insertion of a shunt graft feasible even at this late stage in the development of peripheral ischæmia.

The lower leg vessels are rarely the site of initial thrombosis in atheroma and gangrene only results when the thrombosis is extensive in both anterior and posterior tibial, or in the case of digital gangrene, when the digital arteries are occluded. In the presence of main vessel thrombosis of limited extent, the lower leg vessels are often healthy and patent. As the collateral circulation fails, thrombosis occurs in the lower leg vessels, often in multilocular fashion, and further clinical deterioration is inevitable. The occurrence of secondary thrombosis in the lower leg vessels is an important event, because any arterial restoration procedure on the main vessel may be compromised.

The final stage is gangrene, resulting commonly from involvement of the lower leg vessels either by propagation of thrombus from the main vessel or, more commonly, by multilocular thrombosis within them (Table I). Extensive small vessel thrombosis and digital thrombosis are fairly uncommon. Peripheral arterial embolism and extensive degenerative disease with thrombosis together comprise about 25% of all cases. In the latter, there has been no

TABLE I.—PATHOGENESIS OF GANGRENE IN 43 CASES

Extensive main vessel thrombosis	26
Extensive degeneration and thrombosis ..	6
Extensive small vessel thrombosis	2
Digital thrombosis	4
Peripheral embolism	5

evidence of prior peripheral arterial insufficiency. Thrombosis, the result of atheroma, commences at more than one point in an extensively diseased arterial tree, and as there is no collateral circulation extends rapidly. The prognosis in this gangrene of the aged is bad and major amputation inevitable.

It is apparent that in approximately 60% of cases, gangrene is the culmination of many years of increasing peripheral arterial insufficiency caused by the slow extension of main vessel thrombosis and finally precipitated by involvement of the lower leg arteries. Although in certain cases even after gangrene results, the limb may yet be saved, as Professor Rob has shown, surgically the problem is more easily dealt with at some time prior to the onset of gangrene. However, once the stage of femoro-popliteal thrombosis has been reached, the time available for such surgery is limited, as most patients with rest pain and skin changes in the foot develop gangrene in 1 to 6 months.

THE USE OF SHUNT ARTERIAL HOMOGRAFTS

The shunt or by-pass arterial graft has certain technical advantages. Of great importance is the fact that the anastomosis can be kept at a workable size, as the graft obliquely cut or divided up one aspect can be jointed to any length of slot in the host artery even if the latter is small. Exact matching of graft and host artery is not necessary and the suture line is always the widest part. The prepared end of the graft is first sutured to the host artery by the insertion of an everting mattress suture at each end of the incision in the host artery, thereafter a continuous over-and-over suture is quite satisfactory, and during suturing the host artery wall is best penetrated from within out to avoid any possibility of pushing thickened or calcified intima off the media.

Among the advantages are the preservation of all collateral channels and the feasibility of locating the anastomoses, both proximal and distal, at the most suitable points.

Our experimental experience with over 70 cases using homologous artery, autogenous vein and crimped nylon as shunts in small arteries (Hinshaw *et al.*, 1956) indicates that from the point of view of both early and late thrombosis an arterial homograft is to be preferred. My clinical experience is limited to 22 cases. There are two groups of cases:

The first group consists of patients with occlusion of the superficial femoral artery. All these patients had calf claudication as their main complaint. None had rest pain, and except for one case, none had skin changes referable to the foot. Average age was 57 years, and average length of graft 13 in. Pre-operatively, no ankle pulses were palpated. In each case, except one, arteriography revealed a healthy proximal popliteal, and the distal anastomosis was fashioned here. In the remaining case, the proximal popliteal was considered markedly atheromatous, and the site for the distal anastomosis was the distal segment of popliteal artery.

In cases of femoral artery thrombosis, irrespective of the extent, the progression of secondary thrombosis is such that the proximal anastomosis should always be proximal to the profunda femoris origin. In this way the profunda femoris origin serves to protect the orifice of the graft from propagating thrombus. The distal anastomosis can be to either the proximal popliteal if this is healthy, or if it is not, to the distal segment of the popliteal artery. The latter may be the better choice in many cases as the distal orifice of the graft is protected by the numerous collaterals arising from the mid-part of the popliteal artery. In cases of popliteal artery thrombosis of limited extent which are amenable to a shunt graft, the proximal anastomosis may be better fashioned proximal to the profunda origin, although further experience in such cases is necessary.

In all cases post-operatively, the patient developed a warm comfortable foot and symptoms were completely relieved. In each instance, except for the case with skin changes, both anterior and posterior tibial pulses were palpated. The longest follow-up period is fourteen months. In one case, that with skin changes, already referred to, the graft thrombosed after five months. This occurred during the night and resulted in the immediate return of calf exercise pain next day. It is considered significant that this patient had small-vessel atheroma with thrombosis. The immediate post-operative hyperæmia, expected after grafting (Rob, 1953), was very limited, and no ankle pulses were noted.

The second group consists of cases with femoro-popliteal thrombosis. All these patients had calf exercise pain with an exercise tolerance of under 100 yards in each case, rest pain and ischæmic

changes in the foot, and two had gangrenous lesions. Average age was 64 years, and average length of graft 20 in. Post-operatively, symptoms were relieved in each case and the gangrenous areas healed. No post-operative ankle pulses were noted except in one case, in which the anterior tibial pulse was palpated.

In cases of femoro-popliteal thrombosis, the graft has to run from the main vessel just proximal to the profunda to the distal patent segment of the popliteal artery. The lower anastomosis should be fashioned first, and an intermediate incision is necessary in the thigh to help tunnelling and positioning of the graft (Figs. 2 and 3).

FIG. 2.

FIG. 3.

FIGS. 2 and 3.—Femoro-popliteal thrombosis, treated by insertion of a 20-in. shunt arterial homograft. Fig. 2 shows the extensive main vessel thrombosis, poor collateral circulation, and short patent distal segment of popliteal artery. Fig. 3 is the post-operative arteriogram, three months after operation.

The longest follow-up period is eleven months. In one instance the graft thrombosed after eight months. This occurred during a two-and-a-half-hour motor-car journey, the patient being a passenger in the back seat. During the journey she felt discomfort behind the knee, and at the end noted return of calf exercise pain. She has since had a lumbar sympathectomy, and her condition remains satisfactory, with no return of rest pain or gangrene.

Sympathectomy has been carried out in the other 4 patients in this group, and they are also on prolonged or permanent anticoagulant therapy, started about four weeks post-operatively.

The one instance of late thrombosis seems the result of prolonged flexion of the knee-joint. Such an experience confirms experimental findings, where constriction of a homograft at the groin in dogs is not uncommon (Mavor, 1956*a*). Patients with long grafts crossing the knee-joint should be warned against sitting with their knees flexed for prolonged periods.

In conclusion, the justification for a grafting procedure in cases of limited segmental thrombosis is uncertain, because the end-result of the operation is unknown. If the shunt graft will remain patent for ten to fifteen years, then the operation is justified. Objections

to the procedure lie partly in the fact that the diversion of blood through a large shunt will reduce the flow through the existent collateral channels, which may not enlarge or may even thrombose.

In cases of femoro-popliteal thrombosis, operation appears justified. The prognosis as regards gangrene in such cases is usually bad; sympathectomy will improve this, but only to a limited extent. Although it may relieve rest pain it will not uniformly benefit claudication, which by this time may be crippling. This, moreover, is the last opportunity to restore the main arterial trunk of the leg, and it should be taken. When gangrene has developed or is impending, cerebral, renal or cardiac manifestations of the disease are not always contra-indications to operation. Associated sympathectomy and permanent anticoagulant therapy may prolong the period of patency of the graft.

Mr. E. C. B. Butler (London Hospital):

In the treatment of gangrene of the feet, apart from vascular surgery, the improvement in results has been mainly due to the control of sepsis by systemic chemotherapy. This is best demonstrated in the better results now obtained in patients suffering from diabetes. During the past six years we have treated 123 cases of gangrene of the feet:

Arteriosclerotic.. ..	51
Thromboangiitis ..	11
Diabetic..	58
Frostbite	1
Embolic..	2
	123

Arteriosclerotic.—Males 47, average age 65, females 4, average age 68.

In 48 of these patients either the popliteal pulse was absent or there was minimal pulsation with the oscillometer below the knee.

Above-knee amputation ..	45	Two died, aged 76 and 82 years.
Sympathectomy	1	Partial relief.
Below-knee amputation ..	1	
Formal amputation toe ..	1	

In our experience below-knee amputation for these cases was not a success; it was done in three patients as a primary operation but the wounds did not heal and a higher amputation was done.

In the three remaining patients of this group the popliteal pulses were palpable and a below-knee amputation was successful. The total mortality was 3·9%.

Thromboangiitis obliterans.—There were 11 males; average age 45.

Most of them had already had lumbar sympathectomy with temporary improvement.

Above-knee amputations were done in 9 cases, below-knee in 2. Healing was satisfactory and there were no deaths.

The majority of these patients rapidly become used to their artificial legs and lead quite active lives.

Diabetic.—For many years it has been realized that infected feet in diabetics fall into two classes.

One has all the signs and features of a spreading infective necrosis due to the blocking of a main vessel. The treatment of this group is the same as in those due to atherosclerosis except that infection is usually present.

The second group occurs in younger patients whose main arteries are patent, but who suffer from trophic disease of the feet with secondary perforating ulcers, osteomyelitis, or spreading necrosis of the tendons or fascia. A major amputation is rarely required as

the response to local surgery is good. The results obtained in both groups of diabetic necrosis have dramatically improved since the introduction of penicillin.

Without penicillin	38 cases		
Absent popliteal pulse	20		
Above-knee amputation		7	2 died
Local surgery		13	2 died
Positive popliteal pulse	18		
Above-knee amputation		1	died
Below-knee		4	2 died
Syme		3	
Amputation of metatarsals		2	1 died
Local excision		8	

6 of these deaths were due to anaerobic gas cellulitis which rapidly turned to spreading gangrene; death was due either to severe toxæmia or a terminal bacteriæmia. The organisms concerned were anaerobic streptococci with fusiform bacilli; *Cl. welchii* was never demonstrated. The total death rate was 20%.

During the past six years 58 cases have been treated.

Popliteal pulse absent 24. Males 8, average age 68; females 16, average age 70.

Treatment:

Above-knee amputation	23	3 died
Amputation toe ..	1	

Positive popliteal pulse 34. Males 11, average age 57; females 23, average age 63.

Treatment:

Above-knee amputation	1	died
Below-knee	8	
Syme	1	
Amp. of metatarsals ..	5	
Amp. of toe or toes ..	14	
Sympathectomy	1	
Excision of dead tissue with grafting	4	
	34	

The overall mortality was 6%; death being due either to cardiac failure or bronchopneumonia. There were no cases of gas infection.

In our hands amputation of the 1st or 5th metatarsal bone is a satisfactory method of treating perforating ulcers.

If simple amputation of the toes is carried out it is generally wise to excise also the head of the underlying metatarsal as otherwise it is apt to necrose and so delay healing.

Embolic gangrene.—Two cases were seen; one in a woman of 44. She had a below-knee amputation but died a year later from another big embolus. The other was a man aged 69 who died from a pulmonary embolus after an above-knee amputation.

Frostbite.—This case occurred in a man aged 34.

In February 1956 he was admitted to the London Hospital. He had spent three nights in an unheated attic with no overcoat. For twenty-four hours his feet had felt numb.

On the day of admission he had walked to a Salvation Army hostel and plunged his feet into hot water.

On examination.—Both feet and ankles were blue, swollen and numb. Despite treatment there was no return of circulation. Bilateral arteriograms showed a normal arterial tree to within a few inches of the ankle-joint. At that point the circulation failed. Eventually a bilateral below-knee amputation was carried out.

Pathological report.—Loss of myoglobin in muscles. Complete necrosis of small muscles of feet. Inflammation and necrosis but no thrombosis in arteries.

Such a severe degree of frostbite in a young man must be rare in this country and even rarer when it occurs in the heart of London.

Mr. Peter Martin (Hammersmith Hospital, London):

Very often the effect of anæmia in the production of symptoms in a patient suffering from ischæmia of the limb is forgotten. Its correction can be a most valuable aid in the treatment of such a patient.

We have been practising artery grafting of the peripheral vessels affected with atherosclerosis for ten years but, until recently, have been disappointed with the results. In our

earlier cases end-to-end anastomosis was largely used and the results were bad. Since we adopted the end-to-side anastomosis, putting in as it were an extra collateral, the results have been most promising and in no single instance where we have undertaken a graft have we failed to relieve the threat of gangrene. We believe it is a surgical error not to do an arteriogram in threatened gangrene from large vessel obstruction.

For the past nine months the only graft we have used in the lower limb is one from the common femoral above to the lower half of the popliteal artery below. We decided this as we have noted that although the superficial femoral artery is frequently diseased, the common femoral is rarely so severely affected. Similarly the lower half of the popliteal artery tends to escape severe disease. We have grafted with success on to a mere stump of patent popliteal artery no more than 1 in. in length, and in a patient whose peroneal artery alone was patent. When a patient has obstruction of one or sometimes two of the vessels in the leg distal to the bifurcation of the popliteal artery success may still be achieved.

As materials for grafts we have used autogenous vein, freeze-dried arterial homograft and polyvinyl alcohol sponge. Autogenous vein is successful and probably the best, but a vein of sufficient size and length to reach from the common femoral to the distal popliteal artery is not easy to get. A freeze-dried homograft is probably almost as satisfactory as autogenous vein and as this can be obtained in sufficient length we have used it extensively. In a few patients when we have not had a suitable graft available we have used polyvinyl alcohol sponge. It has remained patent long enough for gangrene to heal though there is a distinct tendency for it to thrombose after six weeks or two months. In one patient a leak occurred three months after insertion of this type of graft which demanded its removal and the insertion of a freeze-dried homograft in its stead. We no longer use polyvinyl alcohol sponge in peripheral vessel grafting.

Professor J. H. Dible (Postgraduate Medical School, London) said that there had been very little mention of the underlying pathology in these conditions. Much of the disease in the arteries fell upon the medium-sized vessels of the leg below the knee. The changes in these were commonly very widespread and extremely complex, so that the "collateral circulation", which was in fact an opening up of pre-existing vessels, especially those of the intermuscular planes, the subcutaneous tissue and the nerves, was very varied and depended upon the incidence and sites of obstruction in the larger vessels. Thus, if the anterior tibial were blocked near its origin, as is often the case, much of the blood may pass down the posterior tibial vessel as far as the middle of the leg and then, this vessel being blocked in turn, pass by anastomoses to the peroneal which might supply the foot by its anterior and posterior terminal branches. Such complicated disease in vessels of medium size did not offer much prospect of surgical intervention. A characteristic of atherosclerotic disease was the way in which smaller vessels such as the plantars and digitals escaped, whilst the main trunks in the limb were extensively diseased. In diabetes the pathological lesion in the peripheral arteries appeared to be indistinguishable in the diabetic and the non-diabetic. At the present time the speaker could find no evidence of more rapid progress of the disease in diabetic subjects: both diabetics and non-diabetics came to operation at approximately the same age.

The Amyotonia Congenita Syndrome

By JOHN N. WALTON, M.D., M.R.C.P.

Neurological Unit, King's College, University of Durham, in the Royal Victoria Infirmary, Newcastle upon Tyne

EVERY pædiatrician and every neurologist must often have been faced with the problem of determining the nature of the disease process which is responsible for producing widespread and profound muscular weakness and hypotonia in an infant. The term "amyotonia congenita" has been used by many to embrace all cases of early infantile hypotonia, of whatever cause, while others, following Oppenheim's original description, have reserved this label for cases which show signs of spontaneous improvement. All too often, this difference in usage has resulted in regrettable misunderstandings, when one doctor has diagnosed amyotonia in a child with obvious spinal muscular atrophy, and another, encouraged by textbook descriptions of improvement in cases of this syndrome, has given a good prognosis, only to be proved hopelessly wrong by the course of events.

The diagnosis of amyotonia congenita, through common usage, is now generally taken to include all cases in which generalized weakness and hypotonia of the skeletal musculature is present at birth, or is noted within the first three months, and in which there is no clear evidence of any cerebral, skeletal or metabolic disorder. Admittedly, signs of brain disease or metabolic defect are notoriously difficult to elicit in the first few months of life and this is why so many cases with hypotonia symptomatic of systemic disease are initially impossible to distinguish from others with a primary neuromuscular abnormality. Having defined the syndrome it is possible to say that its causes can be divided into three principal groups which are: (1) Infantile spinal muscular atrophy and related syndromes. (2) Symptomatic hypotonia. (3) "Benign congenital hypotonia."

Before discussing the means of differentiating between cases in these groups it will be important to discuss briefly their clinical and pathological features.

(1) *Infantile spinal muscular atrophy and related syndromes.*—Werdnig (1891) and Hoffmann (1893) described the clinical and pathological features of a condition which often affected more than one member of a sibship and began usually in the second six months of life with progressive, flaccid paralysis of the limbs and trunk. The disease was invariably fatal and histological study of the spinal cord revealed that paralysis was due to extensive degenerative changes in the anterior horn cells. When, in 1900, Oppenheim described a condition characterized by a similar muscular weakness and hypotonia of onset at birth, but differing in its tendency to improvement, many authors, including Collier and Wilson (1908) seized upon the age of onset as the crucial point in diagnosing Werdnig-Hoffmann disease from amyotonia congenita. However, subsequent work revealed that most babies presenting with severe hypotonia at or shortly after birth showed the same downhill course as did typical cases of Werdnig-Hoffmann disease of later onset. In such cases the pathological changes, too, were identical (Greenfield and Stern, 1927) and hence the view became current that Oppenheim's amyotonia congenita and the Werdnig-Hoffmann disease were expressions of an identical pathological process, which in cases of the former type was present at birth, while in the latter, the condition began postnatally. Grinker (1927), on the other hand, suggested that while the abnormality in each condition was primarily one of the anterior horn cells, the former was due to a failure of development, the latter to an active degenerative process. Burdick, Whipple and Freeman (1945) believe that in amyotonia congenita there is an abnormality in development of the entire motor system, from the motor cortex to the anterior horn cells, and this view has gained a number of advocates.

These differing opinions have been considered in detail by Brandt (1950) who carried out a follow-up study of 131 cases previously diagnosed as amyotonia congenita or infantile spinal muscular atrophy. He concluded that the course and prognosis of infantile spinal muscular atrophy was not dependent upon the age of onset and within this group of cases it was not possible to identify a syndrome in which spontaneous improvement occurred, nor one in which the disease process had run its course at birth and showed no further progress. In a recent review of 30 cases, Arthuis (1954) has reached similar conclusions, as I have in a follow-up study of 67 cases reported elsewhere (Walton, 1956). It seems

probable that some cases of the condition referred to as arthrogryposis multiplex congenita (Stern, 1923) or amyoplasia congenita (Sheldon, 1932) are due to a similar spinal muscular atrophy beginning in intra-uterine life (Brandt, 1947), even though others may, as Stern suggested, be the result of a congenital limitation of joint movement, perhaps owing to excessive intra-uterine pressure. It may be suggested, therefore, that a similar disorder of anterior horn cells may give rise to the syndrome of arthrogryposis multiplex congenita if it begins early in intra-uterine life, to the initial clinical picture of amyotonia congenita if it develops at, or shortly before birth, and to the typical Werdnig-Hoffmann syndrome if it begins post-natally.

(2) *Symptomatic hypotonia.*—Diagnosis is complicated even further by the fact that a variety of other disorders may give rise to symptomatic muscular hypotonia in infancy. These causes have been discussed in detail by Brandt (1950), by Tizard (1954), and by Sandifer (1955). A number of the disorders which may present in this way are listed in Table I. Many of them were represented in the 25 cases of symptomatic hypotonia which emerged from my follow-up of 109 cases of the amyotonia congenita syndrome (Walton, 1956).

TABLE I.—THE CAUSES OF SYMPTOMATIC HYPOTONIA

(1) *Neuromuscular and muscular disorders:* Progressive muscular dystrophy, Myasthenia gravis, Polymyositis, Infantile polyneuritis.
(2) *Cerebral disorders:* "Cerebral palsy" (flaccid diplegia, congenital athetosis), Cerebral birth injury, Mental defect, Kernicterus, Cerebral lipidosis.
(3) *Nutritional and metabolic disorders:* Rickets, Scurvy, Cretinism, Malnutrition, Cœliac disease, Glycogen storage disease, Chronic infection; or following an acute illness.
(4) *Skeletal disorders:* Osteogenesis imperfecta, Arachnodactyly.
(5) *Other disorders:* Congenital heart disease, Other congenital abnormalities, Spinal cord birth injury.

The clinical features of symptomatic hypotonia. A proportion of cases of the Duchenne or pseudohypertrophic type of muscular dystrophy may show signs of muscular weakness during the first year of life. In only a few of these is hypotonia with excessive mobility at the joints a striking feature, but I have seen at least 3 cases in which this was true. Each of these children was limp and floppy as a baby and tended to "slip through the hands"; they were late in walking and did so clumsily with frequent falls. As they grew older pseudohypertrophy of the calves appeared and progressive deterioration was apparent, but in the beginning, in the absence of a positive family history, accurate diagnosis on the basis of clinical findings alone was virtually impossible. I have seen only 1 case of polymyositis in infancy and few have been described (Bovet, 1936); although this condition may give generalized muscular hypotonia, signs of constitutional upset and of muscular tenderness with subsequent induration and fibrosis of muscles are generally apparent in cases occurring at this age and act as valuable distinguishing features. In myasthenia gravis, too, the ptosis and other evidence of involvement of the cranial musculature, signs which are usually apparent even in infancy, may, when added to evidence of general muscular weakness, be sufficient to demand a therapeutic test with Tensilon or Prostigmin. Polyneuritis in infancy appears to be a rare disease, even though Adams, Denny-Brown and Pearson (1953) considered that this condition may account for many recoveries from so-called amyotonia congenita; I have no personal experience of this condition, and I was unable to find a single case in the records at The Hospital for Sick Children, Great Ormond Street, over a twelve-year period. However, I should imagine that in cases of this type, the muscular weakness and hypotonia would often show a relatively rapid onset, that there might sometimes be evidence of ascending paralysis, and that the cerebrospinal fluid protein would be raised. Three possible cases of infantile polyneuritis giving the clinical picture of amyotonia congenita have been described by Chambers and MacDermot (1957).

In the various cerebral disorders which may be accompanied by severe muscular hypotonia, any infant which is found to have hypotonic musculature following prolonged cyanosis after a difficult labour, may be presumed to have a cerebral birth injury, particularly if other evidence of brain damage is present. The infant with cerebral palsy, too, may have remarkably limp and flaccid limbs, and may show a striking delay in the development of motor skills, while unusual posturing of the limbs with rather sinuous movements may herald the development of athetosis. Generally, in such cases the tendon reflexes are retained or even unusually brisk, and the plantar responses may remain unequivocally extensor long after the usual age. Similar features usually become evident in case of cerebral lipidosis which may also be generally hypotonic in the beginning, but subsequently epileptic manifestations and particularly myoclonus on startle, usually develop. In kernicterus, too, there may be a history of prolonged neonatal jaundice, while associated deafness and evidence of rhesus incompatibility may be invaluable distinguishing features.

Finally in this group we must mention the mentally defective child, whose limbs are often limp and unusually mobile on passive movement, and whose delay in motor development may be much more striking than his relatively slight mental backwardness. The diagnosis of minor degrees of mental defect in infancy can be a matter of the greatest difficulty and may call upon all the pædiatrician's reserves of skill and experience in assessing the infant's behaviour against a background of known variations in normal development.

When one comes to consider the various nutritional and metabolic disorders which I have listed, it is almost possible to dismiss rickets as a disease which no longer occurs in this country, except in infants with renal disease. Usually in this entire group of cases it is apparent that the muscular weakness and hypotonia which the infant shows is a relatively secondary feature and is overshadowed by fever, by wasting or by some other striking features of systemic disease. When generalized hypotonia develops after an acute illness, rapid recovery is usually the rule, but when the condition is more prolonged, careful attention to the dietary history, urinalysis, examination of the stools, radiographs and biochemical studies, revealing perhaps hypercalcæmia or urinary infection with nephrocalcinosis, may solve the problem. The diagnosis of cretinism, too, will rarely present much difficulty to the experienced pædiatrician after the first few weeks of life. It is in the less common cases where muscular hypotonia is the presenting feature, overshadowing the evidence of general disease, that difficulty arises. I remember, for instance, twin baby girls whose limbs were limp and flabby and who made no attempt to sit between the sixth and ninth months of life. They were also somewhat miserable and tended to cry whenever their limbs were handled. It was only after radiographs of the limbs had revealed subperiosteal thickening that it was discovered that these children were suffering from scurvy; their muscular hypotonia disappeared rapidly after treatment with ascorbic acid. In a similar case which I saw during 1955, a boy aged 14 months had strikingly weak and mobile limbs (particularly the legs), could only sit with difficulty and had made no attempt to stand. He also had an enlarged liver and spleen and was found to be a case of glycogen storage disease. It must be mentioned, however, that in some cases of this type there is no hepatomegaly or splenomegaly as the disorder of glycogen storage is confined either to the muscles—when the diagnosis may only be made by histochemical studies of muscle removed by biopsy—or to the ganglion cells of the central nervous system (Clement and Godman, 1950; Krivit *et al.*, 1953).

Among the skeletal conditions which may be associated with muscular hypotonia is osteogenesis imperfecta; in late infancy this condition may present with flabbiness and undue mobility of the limbs but the family history and subsequent development of fractures will generally lead to the correct diagnosis being made. In arachnodactyly, muscular hypotonia is generally slight, though the limbs may always seem to be unusually mobile; here the diagnosis will be made on the appearance of the digits, on the family history and the association of other defects such as arching of the palate or cardiac abnormalities. It should also be remembered that some infants with congenital heart disease (particularly the tetralogy of Fallot) may be limp and flabby, as may others with multiple congenital abnormalities, of, say, heart and skeleton. The diagnosis of the rare spinal cord birth injury is not generally difficult to make, as there is generally severe flaccid paralysis of the lower limbs only, often with sensory loss. And finally, in considering the causes of symptomatic hypotonia, the possibility of misinterpretation of physical signs should be remembered; in some cases of bilateral congenital hip dislocation, for instance, the comparative immobility of the lower limbs may be wrongly attributed to muscular weakness.

(3) *Benign congenital hypotonia.*—This third and smallest group of cases is for many reasons the most important, since in these children the muscular weakness and hypotonia, though initially profound, resolves gradually and a significant proportion of the patients recover completely, without showing signs of any cerebral, metabolic or skeletal disorder. In a follow-up study of 109 cases previously diagnosed as amyotonia congenita, I found (Walton, 1956) that 17 proved to be of this type; these cases have been reported in detail (Walton, 1957). 8 of them (3 male, 5 female) had recovered completely and 9 (4 male, 5 female) had improved but showed some degree of residual disability. Subsequently, I have observed 2 additional cases which I shall describe briefly as illustrative of the condition.

Case I.—J. N. was first seen in 1952 at the age of 18 months. She was born at term by a normal delivery and seemed to thrive but it was soon apparent that all her limbs were limp and "floppy", that they could be placed in unusual positions, and that she tended to "slip through the hands". She made no attempt to sit until she was just over a year old and when seen aged 18 months she was unable to stand, and her trunk seemed to slump when she sat on the floor. There was severe generalized muscular hypotonia but nevertheless spontaneous movements of the limbs were quite good and the tendon reflexes were present. A provisional diagnosis of amyotonia congenita was made. The child was not seen again until 1956. Soon after the previous attendance she had begun to improve and had walked alone, though clumsily and with frequent falls, shortly after she was 2 years old. Improvement thereafter was rapid; on examination in late 1956 at the age of

6 years she walked and ran briskly, hypotonia had disappeared, and it was apparent that she had recovered completely.

Case II.—R. K. was first seen in 1952 at the age of 12 months and then presented a clinical picture similar to that described in J. N. After a normal birth the child appeared to thrive but it was subsequently noted that he moved very little and was limp and "floppy". On examination he was unable to sit; all movements of the limbs were weak, there was a profound generalized hypotonia with striking hypermobility of the joints, and the tendon reflexes were generally depressed. A diagnosis of amyotonia congenita was made; despite the absence of fasciculation of the tongue and although respiratory movement was reasonably good, it was thought that the child might turn out to be a case of progressive spinal muscular atrophy. Subsequently, however, he showed slow improvement, was able to sit at 18 months and took a few steps unaided when nearly 3 years old. When re-examined at the age of 5 he walked reasonably well with slight accentuation of the lumbar lordosis but was unable to rise from the floor without making use of his hands. There was a slight thoracic scoliosis. All the skeletal muscles were unusually small and weaker than the normal; this atrophy and weakness, though not showing the typical selectivity of progressive muscular dystrophy, affected sternomastoids more than the posterior neck muscles and proximal limb muscles more than the distal. Muscular hypotonia and joint hypermobility persisted, particularly at the hips and wrists, but the deep tendon reflexes were all present and equal. Electromyography and muscle biopsy were not performed. This child has shown slow but steady improvement since the age of 3, but from my experience of other similar cases I doubt whether he will recover completely.

These 2 cases illustrate very well the salient features of the syndrome of benign congenital hypotonia and these are summarized in Table II, in which information from the 17 cases previously described is also included.

TABLE II.—THE CLINICAL FEATURES OF BENIGN CONGENITAL HYPOTONIA

	Muscular weakness and atrophy	Hypotonia and joint hypermobility	Respiratory muscle involvement	Tendon reflexes	Prognosis
(*a*) Cases with complete recovery	+	++	−	Normal or depressed	Complete recovery 5–12 years
(*b*) Cases with incomplete recovery	++	+++	±	Depressed or absent	Persisting muscular weakness, atrophy and hypotonia particularly of proximal limb groups

In all cases the EMG was "myopathic" and muscle biopsy was normal

In summarizing the clinical features as I have observed them I think one can say that babies in both groups show a reduction in spontaneous movements of the limbs in addition to generalized hypotonia and an increased range of passive movement of the joints, but that each of these features is of greater severity in the cases which show incomplete recovery. Similarly, respiratory muscle weakness is seen only in the severe cases, in which depression of the tendon reflexes is also more severe. When I say that electromyographic tracings are "myopathic" I mean that in the cases which I have examined, the interference pattern on voluntary effort showed excessive polyphasic and short duration potentials, as seen in myopathic disorders. This finding, which clearly requires confirmation and amplification in future studies, does not necessarily imply an active myopathic process, but may simply mean that many motor units are populated with less than the normal number of muscle fibres. Turning to the muscle biopsy findings, it is true that in 6 of the cases which I have seen, specimens of muscle obtained at biopsy showed no abnormality when stained with conventional techniques. It is worth noting, however, that Coërs and Pelc (1954) and Woolf and Till (1955), who have each studied single cases which may be of this type, using intravital staining of motor end-plates with methylene blue, found that the end-plates were "immature".

Considering now the relationship of benign congenital hypotonia to other conditions previously described, I believe that many of the cases described by Sobel in 1926 under the title of "essential or primary hypotonia" were of this type. Some of his cases, however, were probably examples of "congenital laxity of the ligaments", which seems to be a separate disorder, since it is often inherited, and the excessive mobility of joints (as seen in contortionists) persists throughout life, but there is no muscular weakness, delay in development, or physical handicap. The cases which recover incompletely are strikingly reminiscent of the "benign congenital myopathy" described by Turner (1940, 1949) save for the fact that his patients showed a selective muscular atrophy like that of muscular dystrophy and in one of them pathological changes in the muscle were found which were

interpreted as myopathic in type. However, it seems possible that these pathological changes, consisting of areas of focal degeneration and phagocytosis of muscle fibres, were related to the terminal illness, namely bacterial endocarditis, from which the patient died after a long period in bed; changes of this type are usually seen only in rapidly progressive cases of muscular dystrophy and would be unexpected in a benign, long-standing myopathic disorder. My cases with residual disability show an even closer resemblance to the condition of "congenital universal muscular hypoplasia" described by Krabbe (1946) and Ford (1952). I have given reasons (Walton, 1957) for suggesting that Turner's "congenital myopathy", Krabbe's "universal muscular hypoplasia" and "benign congenital hypotonia with incomplete recovery" must be closely related, if not identical.

When we come to consider the ætiology of this clinical syndrome, the findings of Coërs and Pelc (1954) and of Woolf and Till (1955) suggest that in certain cases it may be due to an immaturity of the neuromuscular apparatus, which is sometimes overcome by the processes of postnatal development but in other patients is too severe for this natural adjustment to occur. There are, however, many other possible explanations which require exploration by means of electrophysiological, biochemical and neuropathological techniques. I should prefer to conclude by considering briefly some of the principles of differential diagnosis in cases of infantile hypotonia.

Differential Diagnosis

From the point of view of the practising physician, this is the most important problem of all and it is one which bristles with difficulties. If the prognosis is to be foretold with any degree of confidence, it is essential to decide at the earliest possible moment whether the child is suffering from spinal muscular atrophy, from symptomatic hypotonia, or from the syndrome of benign congenital hypotonia. If the diagnosis is spinal atrophy then the prognosis is grave and treatment of no avail; if symptomatic hypotonia, the prognosis is that of the underlying condition, for which specific treatment may be required; while if benign congenital hypotonia is diagnosed a guardedly favourable prognosis may be given until it becomes apparent whether the child will recover completely or incompletely, and in the meantime physiotherapeutic supportive measures and appliances to prevent deformities (such as spinal jackets in occasional cases) may be needed. In Table III I have tried to bring together a number of the points which may aid in differential diagnosis.

Table III.—The Differential Diagnosis of the Causes of Infantile Hypotonia

	Muscular weakness and atrophy	Hypotonia and joint hypermobility	Respiratory muscle involvement	Fasciculation of tongue and bulbar involvement	Contractures and skeletal deformity	Tendon reflexes	Signs of other systemic disease	EMG	Muscle biopsy	Natural history
Spinal muscular atrophy	+++	+++	++	+	++	−	−	Neuropathic	Denervation atrophy	Progressive
Symptomatic hypotonia	±	+(+)	−	−	±	+	+	Often normal, or else that of the primary disease		That of the primary disease
Benign congenital hypotonia	++	++	±	−	±	±	−	Myopathic	Normal	Improvement

Muscular weakness and atrophy are, of course, most severe in the cases of spinal muscular atrophy; although in the infant this atrophy may be concealed by adipose tissue, it can often be demonstrated by soft-tissue radiographs. The characteristic picture of the virtually immobile child, who lies with the arms abducted and externally rotated and with hips abducted and knees flexed, scarcely moving except to breathe, is very characteristic. On being lifted the child is limp and unresisting, tending to slip through the hands, the so-called "rag-doll" baby. Although weakness, hypotonia, and a very obvious increased range of passive movements at the joints are equally a feature of children with benign congenital hypotonia, children in the latter group always show some spontaneous mobility of the limbs and are never so completely paralysed as the severe cases of spinal muscular atrophy. In cases of symptomatic hypotonia, weakness and hypotonia are usually even

less; nor do these cases show respiratory muscle involvement, with recession of the lower ribs at the diaphragmatic attachment during inspiration, a feature which is sooner or later invariable in cases of spinal muscular atrophy and only occurs to a limited extent in the most severe cases of benign congenital hypotonia. Fasciculation of the tongue, too, and other evidence of bulbar involvement such as pooling of secretions in the pharynx, occur only in cases of the Werdnig-Hoffmann type. In similar cases which survive into the second year of life, muscular contractures and severe skeletal deformities, secondary to muscle weakness, invariably develop. Such phenomena are uncommon and relatively slight in cases of symptomatic and benign hypotonia. Furthermore, depression of tendon reflexes is most severe in cases of the anterior horn cell disease, and is less striking in examples of benign hypotonia, while in many of the symptomatic cases the reflexes are normal or even unusually brisk. Also, as I have mentioned, in cases of the latter type there may be signs which indicate the nature of the primary condition, of which generalized hypotonia is but a symptom.

So far as investigations are concerned, the electromyogram in spinal atrophy may show spontaneous fibrillation in a considerable proportion of cases, while volitional activity usually takes the form of repetitive large and broad motor unit potentials; in symptomatic hypotonia the record will generally be normal. My findings suggest that in benign congenital hypotonia the interference pattern of voluntary effort will often show excessive polyphasic and short duration potentials, similar to those seen in myopathic disorders. However, it should be remembered that electromyography may be difficult to carry out satisfactorily in young infants. Muscle biopsy, on the other hand, may be of the greatest value, since in spinal muscular atrophy it will reveal the characteristic atrophy, in groups, of muscle fibres, which is characteristic of denervation, while in the other two groups of cases muscle specimens when studied with conventional techniques will usually be normal, except when the hypotonia is symptomatic of some other muscular disease. Finally, we must mention that the natural history of the illness will eventually make diagnosis certain, as cases of spinal atrophy will become progressively weaker, those of benign hypotonia will improve, and in those with symptomatic hypotonia the nature of the underlying disease will surely become apparent.

I do not wish to imply, by formulating these principles of differential diagnosis, that it is an easy matter. In many cases it will be impossible to be certain of the true state of affairs after a single examination and it may be necessary either to await the course of events, a decision which will inevitably cause some distress to the child's parents, or to arrange investigations in hospital, in the hope of reaching an early decision. Even then there will undoubtedly be difficult cases in which only time and repeated observation will solve the problem; but I hope that some of the information I have given may be of help in allowing an accurate prognosis to be made earlier in an increased proportion of cases.

Dr. **J. G. Greenfield** congratulated Dr. Walton on his clarification of what had been a very confused subject. In his opinion this confusion was chiefly due to Oppenheim, who had diagnosed as myatonia congenita many cases which later progressed and on pathological examination showed the lesions described by Werdnig and Hoffmann. On reviewing the literature in 1927 (*Brain*, 50, 652) he found that in all except two of the fatal cases, in which the diagnosis of amyotonia congenita had been made up to that time, the lesions were identical with those of the Werdnig-Hoffmann type of paralysis. In the other two cases the clinical features indicated a central lesion of the brain or cerebellum. But at that time he was aware of the familial cases later published by Dr. Aldren Turner. In 1955 he had seen two cases in the United States which corresponded to Dr. Walton's description of benign congenital hypotonia. In both cases the proximal muscles were chiefly affected and in both, muscle biopsy showed quite normal muscle. Biopsy was a valuable aid to diagnosis and prognosis, but it must be remembered that in very young infants all the muscle fibres were of small size, otherwise there might be confusion in the interpretation of the histology. He agreed with Dr. Walton that the name "Amyotonia congenita" should be dropped and the name "Benign congenital hypotonia" used for cases of this kind.

Dr. **A. L. Woolf** said that Oppenheim (1900), in an admirably concise report headed "Myatonia in Early Childhood", had drawn attention to a number of infants he had seen, who showed a remarkable degree of hypotonia or even atonia, which seemed to date from birth. Several of these children had improved in the course of time and Oppenheim, therefore, believed the condition resulted from a retardation in development of muscle or anterior horn cells, rather than an acquired disease of the nervous system.

From a study of the literature, it seemed clear that most of the confusion over the relationship of amyotonia congenita to Werdnig-Hoffmann disease had resulted from the difficulty in distinguishing the two conditions by clinical examination alone. Oppenheim (1908) recognized this and emphasized the importance of the clinical history. He was no doubt referring to the early onset and tendency to spontaneous improvement which were characteristic of the cases he was describing. It was possible that Oppenheim did not realize that Werdnig-Hoffmann disease could manifest itself in the first six months of life, but as far as the written word was concerned it appeared that we must hold Rothmann (1909) responsible for the suggestion that congenital cases might be considered as Oppenheim's disease and cases of later onset as of the Werdnig-Hoffmann type. This suggestion, unfortunately, appeared to have been adopted, and the morbid anatomical basis of Oppenheim's disease deduced from histological examination of spinal cords from cases which were really examples of Werdnig-Hoffmann disease, true cases of amyotonia congenita, by their very nature, being unlikely to come to post-mortem examination. It was little wonder that it became accepted that the anatomical basis of amyotonia congenita and Werdnig-Hoffmann disease was the same and that they were, in fact, one and the same disease.

Henceforth, the two terms were used interchangeably. Dr. Walton had more sharply defined the clinicopathological entity of Werdnig-Hoffmann disease and emphasized that it might have a congenital or even antenatal, onset. He had shown some of the remaining cases might be due to a variety of causes, including a group which could not at present be further broken down and which resembled closely those described by Oppenheim as myatonia congenita. Dr. Woolf suggested that these cases were, in fact, examples of Oppenheim's disease that Dr. Walton had rescued from the miscellaneous group of infantile hypotonias, amongst which their special nature had for so many years been lost sight of, owing to the indiscriminate application to all the cases in the group, of the term amyotonia congenita. Dr. Woolf further suggested that, henceforth, recognition should be given to Oppenheim's service in drawing attention to the congenitally floppy baby with good prognosis, by retaining his term myatonia congenita or amyotonia congenita, but that it should be made clear that not every case of hypotonia, with a congenital or antenatal onset, fell into this group.

With the possibility of diagnosing amyotonia congenita in life, the opportunity of defining the changes in the muscle and intramuscular nerve endings by muscle biopsy became more favourable and might thus result in a useful diagnostic aid.

Dr. Woolf briefly described three cases. The first (case of Dr. B. S. B. Wood), a child of 10 months with the clinical features of amyotonia congenita, showed a muscle completely normal in all respects. Bielschowsky preparations showed a rich innervation. Acetyl cholinesterase preparations showed large numbers of subneural apparatuses of end-plates, which were just as complex, though naturally smaller, than those of an adult. Vital staining with methylene blue showed end-plates only slightly less elaborate than those of a normal child aged 1 year (preparation kindly lent by Dr. C. Coërs). This child, shortly after muscle biopsy, rapidly improved, the tendon reflexes even becoming brisk. There had been a blood urea of 54 mg./100 ml. but there was no other evidence for a biochemical disorder as the basis of the condition, and at any rate, biopsy had foretold the favourable outcome.

The second child (case of Dr. H. Parry Williams), aged 2 years 4 months, also showed the clinical features of amyotonia congenita. The muscles were very slender indeed, as seen in radiographs, and there was a flexion deformity of the outer three fingers on each side. Muscle biopsy did not show any definite abnormality in hæmatoxylin and eosin preparations, but acetyl cholinesterase preparations showed few end-plates, and those present appeared to contain little acetyl cholinesterase, only a few crystals of brown staining material being present even after three and a half to twenty-four hours' incubation. Vital staining with methylene blue showed many end-plates and nerve fibres. Some of the end-plates were poorly formed or bizarre, but many were as mature as in the adult. The course of the nerve fibres across the muscle fibres was more oblique than normal, although muscle fibres had been lost. There were also some fine beaded sprouting nerve fibres. The significance of these findings was obscure but they did not strikingly suggest immaturity.

Finally, Dr. Woolf referred to a case of myasthenia gravis (Dr. E. R. Bickerstaff's case), who had always been slow in his movements, but had recently, at the age of 12 years, developed a ptosis of myasthenic type with good response to Prostigmin. Vital staining with methylene blue and acetyl cholinesterase preparations showed that, while the majority of the end-plates were of "adult" type, a minority consisted only of one to three simple spherical expansions, grouped closely together so that no terminal arborization could be seen. The significance of these immature looking end-plates is not yet clear but it is obvious that this appearance must not be regarded as diagnostic of amyotonia congenita.

The Histochemistry of Normal and Abnormal Human Muscle

By E. B. BECKETT, B.Sc., and G. H. BOURNE, D.Sc., D.Phil.

Department of Neurology, The London Hospital and Department of Histology, The London Hospital Medical College

Introduction.—Muscle is made up of fibres, the structures (motor end-plates) which innervate them, and the connective tissue which binds them together. The fibres are themselves composed of (i) the contractile elements, and (ii) the sarcosomes which occur between them. Of the two main metabolic pathways by means of which glycogen is oxidized to produce energy the group of enzymes concerned with the anaerobic path are concentrated in the contractile portion and those concerned with the aerobic pathway in the sarcosomes.

Suitable techniques are not available for the histochemical demonstration of the first group of enzymes but techniques are available for the second, particularly succinic dehydrogenase and cytochrome oxidase which are largely concentrated in the sarcosomes; and these were among those used in this study. It was thought that as well as making a study of the enzyme activity of these bodies, observations should also be made of their general shape and appearance.

MATERIAL

Controls.—In this work controls were obtained at one-hour *post mortem* from two young healthy adults and four specimens were obtained within twelve hours of death from elderly people. A few control specimens of doubtful value were also obtained—one was taken during a cup arthroplasty (in this the muscle was definitely abnormal) one was taken at amputation of a limb which had been immobilized by accident and disease for twenty-five years (in this the muscle showed simple atrophy), and some specimens were also taken from the abdomen at operation.

All diseased muscle used for comparison with these controls was taken by biopsy and was put straight on to solid carbon dioxide in a sealed glass jar. The histochemical techniques were usually commenced on such samples of muscle within fifteen minutes of its removal from the body. All biopsy specimens were taken from the motor point as indicated by surface and direct faradic stimulation. The muscle chosen for biopsy was one in which functional changes were rapidly taking place. The diseases from which biopsy material was obtained included: facio-scapulo-humeral dystrophy, pseudo-hypertrophic dystrophy, familial dystrophy, polyneuritis, polymyositis, motor neurone disease, peroneal muscular atrophy, several neuropathies and myopathies of unknown origin, carcinomatous neuropathies and myopathies.

RESULTS

Sarcosomes.—A. *Structure.*—Heidenhain's iron hæmatoxylin method was used to demonstrate the sarcosomes. In rat muscle a number of elongated structures were found to be demonstrated by this method, and in human muscle many small rounded structures were seen. Some doubt was felt as to whether these structures were, in fact, sarcosomes. In a number of specimens of dystrophic muscle these rounded structures did not appear to be demonstrated and in many cases they appeared to form elongated strands of material which took up the stain strongly. However, similar structures were found in normal muscle which had been subjected to trauma. But this condition was found more often in dystrophic than in normal muscle, which suggests that if it is due to collapse of the sarcosomes, then the latter are more fragile in dystrophic muscle. This problem cannot be adequately solved until the precise identity of the hæmatoxylin-staining structures are known, and this will require electron microscopy.

B. *Enzymes.*—A histochemical test for succinic dehydrogenase was used, the technique being that of Seligman and Rutenburg (1951) as modified by Shelton and Schneider (1952).

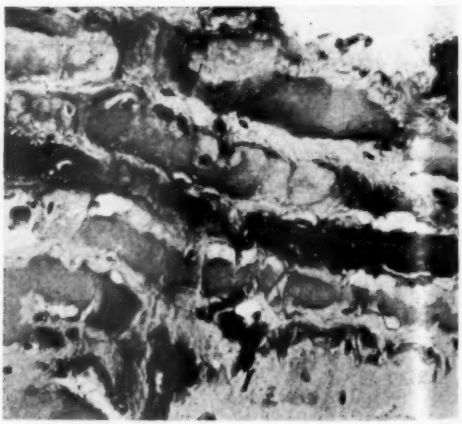

FIG. 9.—Muscle from a case of familial dystrophy, showing a large concentration of 5-nucleotidase in connective tissue fibres, in invading cell nuclei and in some atrophied muscle fibre. × 160.

In normal human muscle there was considerable variation in the intensity of the reaction. This was due partly to a random variation from unknown causes and partly to the fact that the reaction varied quite considerably in different muscles. The succinic dehydrogenase activity varied quite independently of the cytochrome oxidase. In general, we found that the intensity of the reaction tended to be decreased in pathological muscle, indicating a lower aerobic metabolism, but it was not possible to find any correlation with clinical diagnosis. In cases where the muscle was largely replaced by connective tissue there was, as might be expected, a very considerable reduction of the reaction.

Fibres.—The structure of the contractile elements could not be investigated without facilities for electron microscopy which we did not possess and suitable techniques were not available to study the enzymes located in them which are concerned with anaerobic respiration.

Motor end-plates.—An investigation of the structure of these bodies was not carried out but a study of their cholinesterase activity was made. The technique used did not employ formalin fixation. This type of fixation has been used by other authors but we felt that it should not be used in the present work since it is known partially to inhibit the enzyme in many tissues (Taxi, 1952, and Couteaux and Taxi, 1952) and we have shown it to inhibit completely the reaction in human fœtal muscle. The technique used was Gomori's (1952) modification of Koelle and Friedenwald's (1949) method and the specificity of the reaction was controlled by the use of eserine.

Two types of cholinesterase-positive structure have been found in human muscle (Coërs, 1953 and 1955). These are the type known as the "classical" end-plates or "terminaisons en plaque" and the "terminaisons en grappe". The first of these consists of a ribbon-like gutter structure twisted upon itself; and the second of small round gutter structures grouped together without any particular connexion between them and often covering an area of considerable size. This latter type seems to be characteristic of human muscle and does not appear to occur in the muscles of experimental animals. Two other cholinesterase-positive structures which have been found are the motor end-plates which occur at each end of the intra-fusal fibres of muscle spindles, and structures situated at the ends of the muscle fibres at the musculo-tendinous junctions, described by Couteaux in 1953 in frog, mouse and fish and by Gerebtzoff (1956) in the muscles of a variety of animals including humans. All of these structures have been seen in the human muscle which we examined, the "classical" plates usually being found to be arranged in rows across the muscle.

We very rarely found any decrease in the cholinesterase activity of any of these structures in pathological conditions. However, in muscle from a case of peroneal muscular atrophy and one from a case of polyneuritis there was some decrease in the reaction intensity in cholinesterase-positive structures at the musculo-tendinous junctions.

We found perfect "classical" end-plates with full cholinesterase activity in muscle obtained from a case of motor neurone disease. In several pathological muscle specimens some previously undescribed cholinesterase-positive structures were found. For example, objects consisting of parallel gutters arranged like a "cake-frill' 'could be seen. These appeared to be normal structures although we have not so far observed them in normal specimens of human muscle. It is possible that they represent some type of stretch receptor. A structure composed of a "shower" of parallel gutters was also seen, and one which in cross section appeared to be in the form of a gutter wound spirally round a muscle fibre. In the piece of iliacus muscle taken from a patient undergoing cup arthroplasty for osteoarthritis there were areas containing small "dots" of cholinesterase activity and in many cases the muscle fibres appeared to possess enzyme activity diffused through the substance.

One of the most striking observations which have been made in this work is that in some cases where most of the muscle has been replaced by connective tissue (for example, in familial muscular dystrophy) remnants of muscle fibres can be seen floating in a sea of connective tissue but possessing end-plates which appear normal in structure and possessing undiminished enzyme activity. In fact, one gains the impression that the possession of cholinesterase activity within a gutter-like structure retards the destruction of that particular area of muscle. It is of interest, however, that when muscle fibres are undergoing atrophy (but not simple atrophy) they appear to develop considerable diffuse cholinesterase activity. Even normal human muscle fibres contain a certain amount of diffuse cholinesterase activity (inhibited by eserine)—a fact which is not recorded by other authors.

Connective tissue.—The connective tissue of muscle has been thought of largely as a structural component and to have function only in the sense that it serves as a support for the nerves and blood vessels which supply the muscle fibres. The results obtained in this work suggest, however, that it may play a very active part in the development of many dystrophies.

This has been shown by the use of a technique which demonstrated the enzyme 5-nucleotidase. The technique was that of Gomori (1952). This enzyme splits muscle adenylic acid, which is adenosine monophosphate, and which is used as a starting point for the re-synthesis of A.T.P.

When this technique is applied to normal human muscle there is very little reaction shown by any of the tissue elements with the exception of the walls of the larger blood vessels and nerve fibres. In one sample of control muscle where there were signs of inflammation, the inflammatory cells gave a positive reaction. However, it was found that about one-quarter of the pathological specimens examined showed a great increase in the reaction for this enzyme in the connective tissue, particularly in cases of muscular dystrophy characterized by atrophy of fibres and increase of interstitial connective tissue. This was also found in one case of myopathy and one of motor neurone disease. In other pathological specimens there was only a small increase in enzyme activity. There was no correlation between the increased occurrence of this enzyme and the type of clinical diagnosis. Muscle fibres which were undergoing degenerative atrophy were found to have this enzyme diffused through the atrophying portion. In the connective tissue, fibres, cells and capillaries appeared to be invading and destroying the muscle fibres, and each of these elements gave a strong 5-nucleotidase reaction.

It appears from this that one of the features of many dystrophies is active physical and chemical destruction of the muscle fibres by the connective tissue which normally supports and nourishes it, and it seems possible that some inhibitory substance for this enzyme might find a place in the treatment of dystrophies.

Dr. A. L. Woolf in discussion on Dr. Bourne's paper said that some of the subneural apparatuses in acetyl cholinesterase preparations, with an increased number of small, darkly staining elements, resembled those he had seen in cases with evidence of reinnervation in methylene blue preparations.

Dr. H. S. Baar asked Dr. Bourne what tetrazolium salt he had used. In his experience for quantitative estimation of succinic dehydrogenase in tissue homogenates in the presence of an excess of substrate only mono-compounds were useful. For histochemical demonstration best results were obtained with bis-compounds, particularly with the blue tetrazolium. The blackish-blue diformazan at sites of high activity contrasted beautifully with the red monoformazan at sites of low activity. The small size of crystals permitted also the localization of succinic dehydrogenase in sarcosomes. What was Dr. Bourne's experience on the glycogen content of muscles in cortisone-treated myopathies? The speaker had the opportunity to examine a fatal case of dermatomyositis which had been treated with cortisone and prednisolone for one year. Active muscles contained little glycogen but the soleus muscle which was inactivated because of fibrous contracture of knees and showed no fibrous replacement was studded with innumerable granules of glycogen. Even in the gastrocnemius, which showed advanced fibrous replacement, fragments of the degenerated muscle were recognizable as short cylindrical accumulations of glycogen within fibrous tissue.

Dr. J. N. Walton said that Dr. Bourne and Miss Beckett had mentioned the hypertrophied muscle fibres which they saw very commonly in their cases of muscular dystrophy. Did their observations indicate the nature and cause of this hypertrophy; for instance, did the enlarged fibres contain more than the usual complement of fibrils? Did the histochemical studies give any explanation for the remarkable accumulation of fat which appeared between the fibres in some cases of muscular dystrophy; this infiltration often appeared to be far greater than would be necessary for simple replacement of atrophied muscle. Lastly, had Dr. Bourne and Miss Beckett discovered any essential histochemical differences between different muscles or muscle groups? It was very difficult to explain the curiously selective muscular involvement which occurred in muscular dystrophy on the basis of a diffuse biochemical disturbance.

Miss Beckett and **Dr. Bourne,** in reply to Dr. Woolf: The presence of a large number of small darkly-staining elements in an end-plate area is not necessarily indicative of re-innervation (Coërs, 1955).

In reply to Dr. Baar: We used neotetrazolium. We have found histochemically that there is a large variation in the amount of glycogen normally present in muscle. If cortisone had any effect it was not observable in our specimens.

In reply to Dr. Walton: We did no counts of myofibrils, but they did not appear to be increased in size, so that they may be increased in number. We cannot account for the gross increase in fatty tissue observed in some muscular dystrophies.

We have observed some histochemical differences between different muscles and muscle groups. The most striking is the difference observed in succinic dehydrogenase levels.

Muscles and the Teeth

By W. J. TULLEY, B.D.S., F.D.S. R.C.S., D.Orth.R.C.S.

The Dental School, Guy's Hospital

IN recent years much has been written concerning the role of the muscles activating the jaws and surrounding the dental arches; it is convenient first to review some of the basic anatomical and physiological concepts. Muscle is not as responsive to its environment as bone. Bone is constantly being remodelled but the number of fibres in any muscle is fixed. A muscle can only increase in size by hypertrophy as occurs in the leg muscles of athletes but the latter show no significant increase in the size of their bones. The shape and arrangement of a muscle varies considerably from one individual to another.

A skeletal muscle is part of a functional system and never acts as a separate unit; it may be a prime mover, an antagonist or a synergist. Many activities do not normally enter consciousness, movements follow a stimulus as a patterned behaviour. In man, the progressive domination of motor reactions by the highest functional levels of the central nervous system is of considerable significance. Disharmonies in the conscious levels of the mind may be a common source of motor disability and faulty posture and uneconomical use of various muscles may arise due to this.

If a man suffers paralysis of a flexor muscle group, an extensor muscle can be transplanted on to the flexor surface and the function re-learned until a new pattern becomes established. One of the controversial aspects of adverse muscular behaviour related to the masticatory and circumoral muscles has been the statement that their basic patterns of motor activity cannot be changed (Ballard, 1955).

If we apply general principles to our particular field we see that some of the functions of the orofacial muscles are functionally represented at a much higher level in the brain than others. Activities such as swallowing are only under voluntary control in the first stage. Swallowing is a basic reflex behaviour initiated even before birth and it is not unreasonable to infer that changes cannot be readily established by exercises.

Activities such as speech have a high degree of cortical control. It is true to say that some speech defects are due to abnormal neuromuscular anatomy but many are due to defects in learning and are re-educable by conscious effort.

Mastication occupies a position between the function of swallowing and speaking. It can be compared with walking. Each individual develops a characteristic subconscious chewing "gait". This is built up on an underlying co-ordinating pattern in the nervous system but will vary considerably with the anatomical position of the teeth. Abnormal tooth position will be reflected in the masticatory pattern.

Research methods used to investigate normal and abnormal muscular activity in relation to the teeth can be divided into the following groups:

(1) Clinical observation over a long period. This may be recorded by cine film.
(2) Animal experimentation (surgical intervention with unilateral muscle function).
(3) Observations of the effects of pathological conditions affecting muscle function.
(4) Cine fluoroscopy of the soft tissues.
(5) Electromyography and methods of recording muscle forces.

CLINICAL OBSERVATIONS

Most of the valuable contributions to our knowledge of orofacial behaviour have been made by astute clinicians, though Sim Wallace placed too much emphasis on function in relation to form, while Alfred Rogers put an undue emphasis on exercises, as a method of correction of malocclusion.

One of the classics of English orthodontic literature is the *original* publication of Brash's Dental Board Lectures in 1929 and the chapter on soft tissues contains many statements which have withstood the test of time.

Present views can be summarized as follows:

(1) The basic structure of the jaws develops according to a predetermined pattern. However, the potential for growth cannot be determined at any particular time. Function, for example early feeding methods or the consistency of diet masticated, has no effect on the basic growth of the jaws.

(2) The teeth with their alveolar process develop between the influence of the cheeks, lips and the tongue. The relationship of upper and lower dental arches is determined by the size and relative positions of the basal elements of the jaws and reflect the shape, the resting position and activity of the soft tissues.

A rough classification of clinical types can be made, embracing skeletal, dental and soft tissue morphology (Gwynne-Evans and Tulley, 1955). Morphology of the soft tissues may be as inherent as the basic bony structures but there is a controversy concerning the abnormal activity of the muscles.

Rix (1946) focused attention upon the importance of the activities of the tongue and lips, with particular reference to swallowing. He described the atypical teeth-apart swallow in which the tongue did not mould the developing dental arches centrifugally. In 1953 he described many variations on this theme. Rix believes that in some instances a combination of change of tooth position and maturation of behaviour produces a change which is stable. Ballard believes that these patterns of activity are to a large extent endogenous. Gwynne-Evans has pointed out that the circumoral muscles, occupying a developmental position between the somatic muscles moving the limbs and the visceral muscles of the gut, are not so easily controlled by changes in tooth position or by exercises.

The American view is that many of these abnormal activities are habits developed either primarily, or that they are secondary to the dental alignment and they modify with treatment and exercise.

(3) Upper respiratory infections and obstructions, although they often accompany malocclusions, cannot be shown to be the direct cause but only an associated factor. The narrow maxilla is inherited and not due to lack of aeration of the antra. Naturally narrow nasal passages are more easily obstructed, although it is possible to find this facial type without any history of upper respiratory troubles (Fig. 6A).

The constriction of the dental arches on already narrow bases is due to the accompanying pattern of soft tissue morphology and function. There may be a low rest position of the tongue but the lack of lip seal is not necessarily an indication of mouth breathing. The tongue and soft palate form a posterior seal. Lack of lip seal in these cases may be due to anatomically short upper lip, or to separation of lips by the teeth, or to lips which have an innate posture which Ballard calls the incompetent lip posture. All three of these factors may be present.

(4) *Rest position.* The posture of the mandible at rest is a so-called constant for the individual (Thompson, 1946). In the infant the gum pads are widely separated at rest but as the teeth and alveolus develop the inter-occlusal clearance diminishes to 2–3 mm. in the molar region. The normal path of closure from rest to occlusion is a simple hinge movement.

Abnormal alignment of one or more teeth may act as a displacing factor to the normal path of closure. Grewcock and Ballard (1954) and others have described true overclosure in postural Class III and some Class II Division 2 malocclusions. This comes about by premature contact of teeth and sensory impulses from the supporting tissues of these teeth initiate a reflex avoiding pattern. The mandibular elevators carry the mandible past the normal centric position. Possibly the abnormal contraction of these muscles restricts the occlusal development of the cheek teeth.

Lateral displacement is also found initiated by abnormal tooth contacts. There is no overclosure in these cases and the correct path of closure is restored by grinding or repositioning of the teeth. In certain instances if the basic shape and behaviour of the circumoral and lingual musculature is responsible for the positioning of the teeth on the basal bones they must indirectly affect the path of closure. Therefore they influence the masticatory pattern, and if this argument is taken to its logical conclusion they might indirectly be concerned in temporomandibular joint disorders.

There are acquired postures of the mandible which are not the true rest position. These may be developed in Class II cases to overcome the inability to seal the lips and mask the retrusive appearance. Brodie calls this the "Sunday face". This is a position of rest established by habit. Some workers have described distal displacement and overclosure in a large number of Class II cases. They have not taken into account this acquired forward postural position and the return to true centric on closure.

Other Research Methods

Animal experimentation has, in the main, been disappointing and misleading. There have been many experiments where there has been surgical or other interference with muscle

function but in nearly every case there has been the problem of scar tissue or lack of proper control.

Observations from pathological conditions affecting muscle function in man may also be misleading but they do illustrate the malleability of the alveolar process. They tend, however, to give a wrong impression concerning changes in basic jaw structure. In the older textbooks, cases of bilateral ankylosis of the temporomandibular joint were often quoted in support of the hypothesis that normal masticatory function was necessary for good jaw development. We now know that it is the growth centre of the condyle that is affected in such instances, preventing mandibular growth.

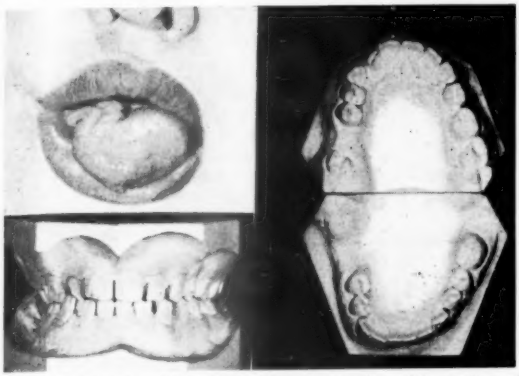

FIG. 1.—A case of right-side VII nerve palsy with section of hypoglossal nerve showing the effect of unilateral tongue paresis on the dental arch.

In cases of unilateral VII nerve palsy which have occurred at an early age during the development of the dentition there is no marked asymmetry of the dental arches, suggesting that the cheeks are not such important factors as the tongue at rest and in function in moulding the dental arches. However, Fig. 1 shows one case of VII nerve palsy where the tongue had also been affected by section of the hypoglossal nerve in an attempted transplant. This case shows a marked asymmetry of the alveolar process on the side with the abnormal tongue position and function. More teeth have been lost on the side where the normal cleansing action of cheeks and tongue was deficient.

In visiting a home for children with various upper motor neurone lesions it was interesting to note how few malocclusions there were among those children with unco-ordinated athetoid movements of the facial and lingual muscles but those with true spasticity of the tongue showed the dominant role of the resting position of this organ.

Cine fluoroscopy. The possibilities of studying soft tissues of the mouth with cine fluoroscopy are improving with the advent of electronic image intensification. A number of studies have already been made, notably those of Ardran and Kemp (1951). Other films of temporomandibular joint and nasopharyngeal closure in cleft palate cases have been made in the U.S.A.

Electromyography. This was first used to investigate dental problems by Moyers at the University of Iowa in 1949. The electromyograph amplifies and records the electrical potentials which develop when a muscle contracts. Much work has already been carried out on the electromyographic study of normal activity and on the type and siting of electrodes.

Moyers, recording from the suprahyoid group, especially the digastrics, has cleared up some of the controversy concerning the role of these muscles in opening the mouth (Last, 1954).

In studying specific functions the electromyograph is able to make progress beyond the purely visual and palpation methods of studying muscular activities.

Eschler in Freiburg has studied the masseteric activities of infants during breast and bottle feeding. His findings show, as one would expect, greater masseteric activity in breast-fed children and even if they had to go on to a bottle at an early age; those that were commenced on the breast continued to show greater suckling activity.

Many workers have been interested in masticatory activity and recordings from cases of normal occlusion agree that the masseter is the power muscle of mastication and the temporal the initiator of the movement and capable of more rapid but less sustained response. They have also shown the muscles of the balancing side may be as active in normal occlusion cases as on the chewing side. In the incision of food the masseter shows activity whereas the temporal, acting at a mechanical disadvantage, comes into play after the initial contact. In studying mastication it is important to obtain a natural setting for the experiment so that the patient does not chew according to a set pattern. The following observations can be made from my experiments which agree with the findings of other workers (Figs. 2 and 3).

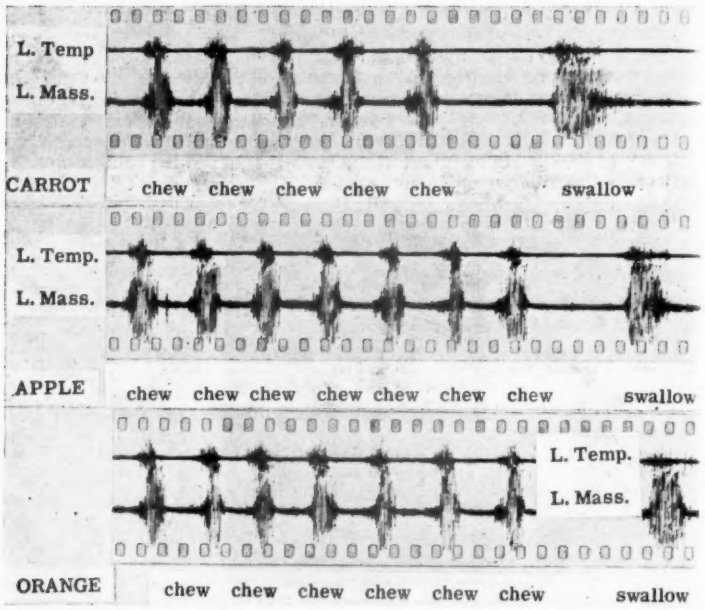

FIG. 2.—Examples of chewing and swallowing behaviour recording from temporal and masseter on a two-channel electromyograph. Note the rhythm, the sequence of contraction.

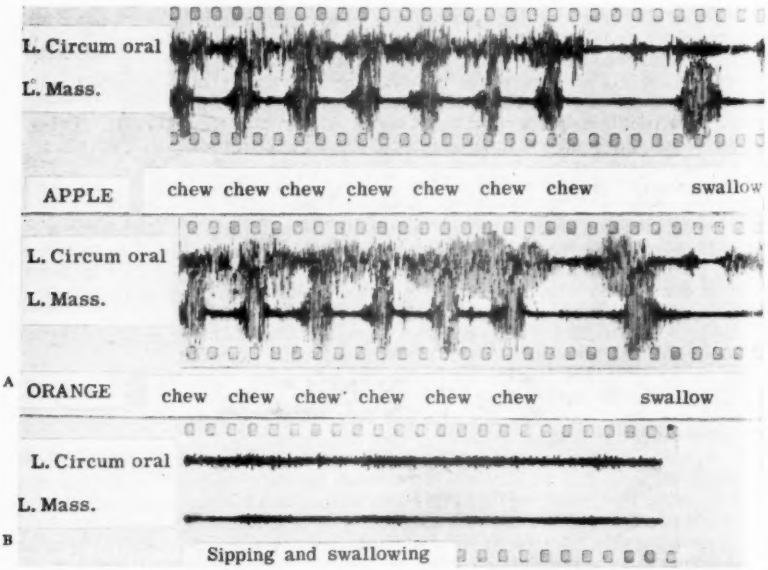

FIG. 3.—A, Examples of chewing and swallowing behaviour recording from circumoral and masseter. Note increased lip activity with succulent material and, B, the minimal activity of masseter during sipping and swallowing.

(1) The uniformity of the masticatory stroke from both masseter and temporal.

(2) The rhythmic activity of cheeks and lips between each masticatory stroke. (The recording from the lip muscles shows a finer pattern with a greater frequency indicating fewer muscle fibres controlled by one nerve fibre.)

(3) There is a wider band of masseteric activity with the same amplitude indicating a totally greater force in chewing the harder foodstuffs.

(4) When recording from temporal and masseter, the temporal contracts slightly in advance of the masseter reaching its peak potentials before the masseter.

(5) There is a definite relationship between amplitude, frequency of contraction and the size and toughness of the material.

(6) Even with normal occlusion there is often a habit or preferred side which is used mainly in chewing. This may have been initiated by some painful tooth or some local stimulus but Eschler has shown this development of a preferred side from early age in the weaned infant.

(7) When chewing on the preferred side the balancing side does not necessarily show as great a contraction of the masseter. However, when chewing on the unusual side the balancing side shows a contraction equal to the muscle on the chewing side.

Coincidently with the investigations of chewing, observations have been made concerning the state of the muscles at rest but there is controversy over the recordings from resting muscles. There would appear to be electrical silence even to the most sensitive apparatus, but at this high amplication, the problems of amplifier "noise" are very difficult. Using a loud speaker as Perry does it is possible to get "audio silence". I have made similar investigations with the lip muscles. Here more than in the masseter and temporal, relaxation is difficult to obtain but there is virtually electrical silence.

My main interest in the use of the electromyograph started with an investigation of normal swallowing activity as described by Whillis and Rix. This was achieved by placing electrodes as is illustrated in Figs. 4 and 5. The electrodes on the masseter were placed along the main course of the muscle, the upper, 1½ in. from the outer canthus of the eye, and the lower, 1 in. from the angle of the mandible.

The electrodes on the lips were placed one on the upper and one on the lower just medial to the corner of the mouth recording the general activity of the orbicular sphincter. Recordings were taken from both sides.

At the moment of swallowing when the mylohyoid muscle contracts there is normally a firm contact of the teeth achieved by masseteric contraction and the amount of lip activity is minimal. The teeth act as a rigid walled barrier to the tongue which is contained within them. Rix has emphasized this as being an important factor in the moulding of the dental

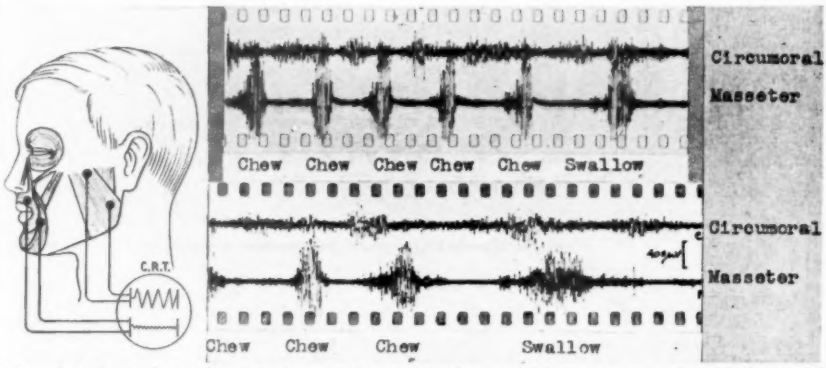

FIG. 4.—Electrode positioning in studying swallowing activities with examples of "normal" (teeth together swallow) after chewing. (From Tulley, W. J. (1956) *Amer. J. Orthodont.*, **42**, 801, by kind permission.)

a ches. In studying examples of chewing followed by swallowing in cases of normal c clusion the following observations can be made (Fig. 4):

(1) In chewing and swallowing of a hard biscuit the masseteric contraction at the moment c swallowing equals that of each masticatory stroke.

(2) The lip activity is minimal in swallowing.

(3) The lip activity is increased in the chewing and swallowing of succulent material such as a piece of orange. The masseter may or may not contract as strongly as this.

(4) In sipping and swallowing liquid from a cup the tongue acts as a conveyor belt and there is little activity from the masseter.

Studies of Malocclusion

Studies on cases of malocclusion allow the following general observations to be made.

Moyers and others have shown an increased activity of the posterior retracting fibres of the temporalis in cases of Class II Division 1 closing from rest to occlusion. They tend to infer that this is an ætiological factor in some types of mandibular retrusion. It has already been stated that many of these cases adopt a forward resting posture to effect a lip seal and these potentials may be recorded from the posterior temporal producing retraction on closure.

Greenfield and Wyke (1956) have also shown this increased activity of the posterior fibres of the temporalis on one side in cases of unilateral displacement of the mandible, as reported by Grewcock and Ballard (1954).

Zwemer (1955) has shown that in a normal subject closing from rest position to occlusion there is no appreciable activity of the masseter and temporalis until tooth contact is reached. In comparing these cases with cleft palates where there is a defect in vertical development of the alveolar process he shows an excessive contraction of the masseter and temporal muscles to reach occlusion. This activity disappears if the excessive inter-occlusal space is diminished by overlays. This supports Ballard's views of the abnormal contraction of the mandibular elevators in postural Class III cases where there is overclosure and in some cases of Class II Division 2 type where there is distal displacement. Ballard points out that the normal relaxation of the closing muscles does not occur following arrival at the level of true centric. This is significant when considering the vertical development of the cheek teeth.

In studies of chewing in cases of malocclusion many authors have shown that there is not the same clear-cut pattern of masseteric and temporal activity. Perry calls it a searching pattern. Pruzansky demonstrates the chopping pattern adopted by patients with adverse cuspal locking. I do not believe, however, that we are anywhere near identifying the particular type of malocclusion from an electromyograph of the chewing activity.

In this study of abnormal swallowing I have been able to apply the work of Rix and show the increased activity of the circumoral muscles in certain cases when the mandible is not fixed to the maxilla by a strong masseteric contraction (Fig. 5). The electromyograph,

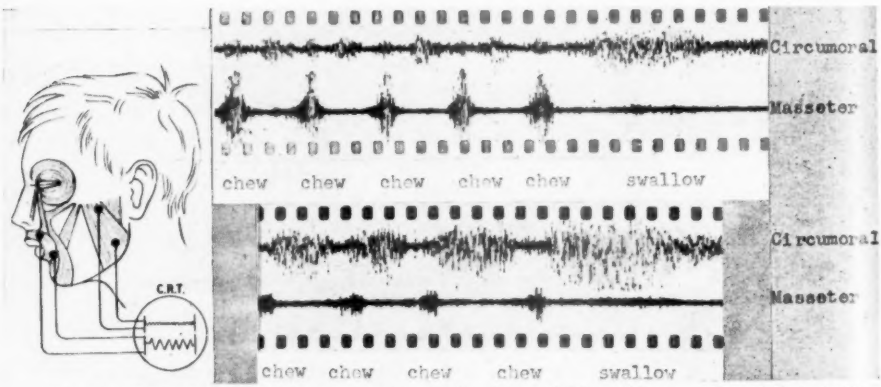

FIG. 5.—Electrode positioning in studying swallowing activities with examples of "atypical" teeth apart swallow after chewing with excessive circumoral activity. (From Tulley, W. J. (1956) *Amer. J. Orthodont.*, **42**, 801, by kind permission.)

however, cannot distinguish the subtle differences in activity of lips and tongue described by Rix (1953).

It has previously been stated that the activity of the circumoral musculature may dictate the position of the teeth which in turn may dictate the masticatory pattern. The deciduous incisors, however, being smaller and not projecting far into the oral cavity are not subjected to adverse muscle forces to the same extent as are the permanent teeth.

Mr. R. E. Rix has allowed me to report a case where there was a normal deciduous dentition

but with the advent of some permanent teeth adverse circumoral forces have influenced the developing permanent dentition to mould an upper arch which is too narrow to receive the mandibular dental arches in true centric. There has been therefore a mandibular displacement in the path of closure to the patient's left. This is an excellent example of a clinical problem and the electromyogram shows the excessive circumoral activity and the type of swallowing behaviour. It also emphasizes the practical point that many malocclusions are not so commonly manifest in the deciduous dentition and even when they are, orthodontic treatment at this age is virtually a complete waste of time.

In cases of acquired postural positions of the mandible some ill-defined electrical activity can be detected in the mandibular elevators. In recent papers Perry and Jarabak and others have shown that where there is the vicious circle of abnormal tooth position, temporomandibular joint disorders and abnormal muscle function, muscle spasm in producing cervical facial pain can be diagnosed by the electromyograph. I feel that we shall hear a lot more about this in the near future. Campbell (1954) forecast the use of this apparatus in studying some types of facial pain.

Ballard, in describing what he calls the incompetent lip posture and morphology, has shown that many patients with lack of lip seal have lips that are anatomically long enough to affect a seal but have a poor posture. He has described how these individuals have to make a conscious effort to seal their lips by contracting the orbicular sphincter and although it may become an almost unconscious habit, it is never permanent. This abnormal activity of the lower lip is one of the factors controlling the position of lower incisors. Ballard has pointed out the electromyographic signs and Fig. 6 B, C is an example.

FIG. 6.—Patient at 8 years and 15 years illustrating: A, the so-called "adenoid facies" without any upper respiratory obstruction, the poor posture of the lips. B, seven years later without any treatment, conscious effort to affect lip seal. C, Electromyogram showing activity of lips in order to maintain lip seal.

Finally, I do not believe that electromyography has any future directly related to clinical dentistry as some writers have suggested but I feel it has a definite place in future research by dental clinicians.

CONCLUSIONS

Experimental results so far seem to indicate little change in treatment from that already adopted as a result of clinical observation.

The answer to many of these changes lies in the fulfilment of the growth potential not only of the skeleton, but of the soft tissues also, and in the maturation of the facial musculature which takes on the "adult" mask. With the increasing worries of raising a family and of income tax, we do not expect to see the same lax lip positions of childhood. With the desire of the young lady to appear attractive, we do not see the same "deadpan" face of the preadolescent (Fig. 6 A, B).

These age changes help the orthodontist but create a new problem. Because the neuromuscular system is affected by emotional states some cases of facial pain may be due to spasm in the masticatory muscles. There would appear to be a need for further work upon the physiology and maturation of normal and abnormal orofacial muscular behaviour.

ACKNOWLEDGMENTS

My thanks are due to Mr. R. E. Rix and Mr. K. E. Pringle for allowing me to show cases of patients under their care at Guy's Hospital Dental School. To my colleagues in the Physics Department who have developed the Electromyograph for my use. To Miss Whiteley of the Dental Photographic Department and Mrs. Rawlins for the illustrations.

President—WILLIAM SARGANT, M.A., F.R.C.P., D.P.M.

[*February* 12, 1957]

DISCUSSION: THE PSYCHIATRIC INDICATIONS FOR THE TERMINATION OF PREGNANCY

Dr. J. D. W. Pearce:

In the United Kingdom abortion is lawful only if done in good faith for the purpose of preserving the life of the mother. In this context life includes health, and abortion is lawful only if other effective treatment does not exist, and if the probable consequence of the continuance of the pregnancy will be to make the woman a physical or mental wreck, whether such a result is likely to be permanent or not. Abortion "to protect the health of the unborn child" is always a felony. In Sweden the 1946 Abortion Act enables abortion to be done lawfully on medical, medico-social, socio-medical, humanitarian and eugenic grounds.

The two essential psychiatric questions to be answered are:

(1) What severe psychiatric disorders are precipitated or seriously aggravated by pregnancy or childbearing, and what is their subsequent history?

(2) Which, if any, of these conditions is abortion likely to relieve or cure? The adverse effects of abortion must also be examined.

Most textbooks say little or nothing relevant. Lewis (1950) says that "the termination of pregnancy is called for on account of the mental condition when there are symptoms of organic psychosis which are likely to get worse, a history of suicidal attempts or infanticide in connexion with previous pregnancies and a depression in this one, or if on other grounds there is a clear risk of suicide or other untoward result of the mental illness, should pregnancy continue—The question must turn mainly on the therapeutic value of terminating the pregnancy".

Tredgold and Tredgold (1953) say: "Mental disorder which appears in the first half of pregnancy, and before the child is viable, usually passes when quickening takes place, whilst disorder arising after quickening usually persists for some time after birth and is unaffected by abortion."

Hart (1929) summed up the indications and contra-indications for therapeutic abortion: for pre-existing psychosis, terminate only very rarely; for schizophrenia arising in pregnancy and for recurrent psychosis not related to former pregnancy, no termination; for recurrent psychosis of pregnancy and puerperium, terminate; for severe reactive anxiety and depression stemming from the pregnancy, termination depends on a question of degree.

In 1931, the Sections of Obstetrics and Gynæcology, Medicine and Psychiatry discussed the medical indications for abortion. James (1931) said that where loss of sleep, of weight, and of insight were persistent and accompanied by mental symptoms, abortion should be considered without too much waiting and seeing.

With modern effective treatment one would expect the indications now to be far fewer, but fully developed psychiatric out-patient services have brought more patients under psychiatric enquiry.

The post-war literature shows but little general agreement on the indications for and the therapeutic effectiveness of abortion. Hobson's (1953) main criterion is the risk of suicide, especially in severe reactive anxieties and depressions. Mental deficiency, psychopathic personality and established mental illness are not, in themselves, indications.

Eastwood and Heuser (1947) think that very few, if any, psychiatrists would abort in any of the psychoneurotic reaction types; in only a few recurrent schizophrenic and manic-depressive psychotics owing to inability to care for the child (and similar social criteria inadmissible here); but in single, young women with resultant self-guilt and self-depreciation, plus strong suicidal drives, each case is to be considered on its own merits. This is a narrow field as it includes only those with fully inturned aggressiveness, not those who slash around with threat of self-destruction.

Kummer (1953) sees pregnancy and parturition as no more than precipitating stresses and not basic causes of associated mental disorders. Important factors are the pattern of previous psychotic reactions (severity, duration, reversibility, relation to pregnancy), the physical constitution of the patient, the religious and other personal beliefs of the patient and her family, the desire for parenthood, and the number of living children. Donnelly (1955), however, dismisses all economic and social criteria.

Kraepelin (1909) observed that abortion was more often a precipitant than an alleviant of mental disease. Ekblad (1955) in his Swedish monograph found that the greater the psychiatric indications for legal abortion, the greater the risk of unfavourable psychic sequelæ.

I wrote to some forty-five psychiatrists and to one general practitioner, in the hope of finding some general measure of agreement on the criteria on which decisions to abort are based, and found this largely lacking.

Many approach the problem by asking three questions:

Is this woman's mental state due to pregnancy?

Will abortion relieve the mental illness?

If so, should she be sterilized?

The answers to such questions are mainly subjectively based. There is relatively little firm knowledge of the course of psychiatric illness in pregnancy and the effects, good or bad, of abortion.

Here are some dogmatic statements from some of my correspondents:

(1) Termination has never had a beneficial effect in any case.
(2) The only criterion is severe, chronic, unremitting schizophrenia worsened by pregnancy.
(3) The only criterion is schizophrenia with a bad family history.
(4) Terminate only in some cases of previous puerperal psychosis and mental deficiency.
(5) Each case is considered on its own relative merits, there being no hard and fast rules.

Four or five of my correspondents accept both of the following criteria:

(1) A clear causal connexion with the pregnancy plus the severity of the illness.
(2) A previous similar illness in childbearing.

Two more accept the first but reject the second whereas yet three more accept the second while rejecting the first.

There is much more agreement about *not* aborting than about aborting. Many do not refer to *schizophrenia* at all and presumably never advise abortion: some say they never abort, but a few do so, e.g. in most cases; or if coupled with a bad family history; or if pregnancy is causing psychological strain; or if it is of the covert type keeping out of hospital. With *depressions*, the great majority do not terminate. Almost all regard the threat of suicide as no indication. Many do not refer to low-grade *mental deficiency*, but one invariably aborts and another sometimes. Most do not refer to *neurotic reactions*, some categorically say they never abort, only a very few do so. In *psychopathic states* one or two will abort if in a state of near-psychotic excitement: the rest never.

Two or three add up the various minor factors, but Donnelly (1955) says "One should have one good reason for doing a therapeutic abortion. Three or four minor ones do not add up to one good one".

Some unusual criteria are advocated by a very few of my correspondents, but the law would not permit the adoption of some of these.

The general practitioner says: The general practitioner can help the psychiatrist because he knows the patient's background and personality. Those who become really psychotic or attempt suicide are candidates for abortion, but this may not clear up the trouble. Such cases are not nearly as common as the woman who is just fed-up because of an unwanted pregnancy. The general practitioner can coax most through the first trimester when the desire to be rid of the baby usually subsides. The distressed women, not obviously psychotic, but with threats of suicide difficult to assess are for the psychiatrist. He would never recommend abortion without a psychiatric opinion, and assumes that the consultant would want the general practitioner's full backing.

Most agree on the need to admit patients to hospital for full study and to collect the facts before reaching a diagnosis. One correspondent says "sheer diagnosis is not enough. The decision to abort or not may rest on other circumstances, e.g. husband, home, chance of adequate psychological help". And most agree that most patients can be safely brought through to full time with adequate medical, nursing and social aid.

The criteria most of us use are based on a tacit assumption that abortion *per se* has a therapeutic effect in a wide but undefined range of psychiatric maladies, and but few of any bad effects. But we need more knowledge about the natural history of psychiatric illness associated with pregnancy, and the late results of abortion, and more studies to provide valid criteria.

Until such time I would advise some curtailment of so much clinical freedom to recommend abortion. There should always be at least two independent psychiatric assessments, and in-patient examination has much to commend it. In Colorado (Ebaugh and Heuser, 1947) since 1937 an abortion committee, which includes the professors of medicine, obstetrics and gynæcology, and psychiatry, decide on each case after full in-patient study: surely an excellent plan.

The regular general practitioner must always be in the picture. I feel insecure about any patient coming from a general practitioner who has seen her for the first time because of her predicament.

Casper (1934) said that scientific men should apply themselves more diligently to the task of saving both mother and child. All our resources—medical, psychiatric and social—should be used to tide a woman over, if needs be as a voluntary in-patient, until quickening, as so many mothers then settle down. Moreover, hysterotomy enables her to be sterilized at the same time if indicated.

I tend to follow Hart's criteria, but I sometimes have misgivings over my rather legalistic attitude. Religion is above medicine, and religious differences are to be accepted, and respected. None the less ethical, moral and social issues inevitably complicate our thinking about this subject. History shows the transient nature of social and eugenic criteria. Ebaugh and Heuser (1947) say that morally the medical profession cannot condone abortion for economic or sociological reasons, but one cannot but wonder what effect it might have on juvenile delinquency, alcoholism, mental deficiency, suicides, homicides, arrests, &c.

Some psychiatrists advocate eugenic abortion. A case may, in principle, be made out for this, but it could be applied only where there were most reliable criteria. It is difficult, indeed impossible, to remain entirely a medical man in considering such a problem. Twenty-six years ago the whole emphasis seems to have been on mental disorder. Now we have the concept of mental health, and a further evolution in our thinking on these matters is under way.

Just before Bourne's trial at the Old Bailey, James (1938) wrote: "It should not be beyond the ability of two learned professions to devise a formula which acknowledges 'reason' to be as important as 'life', and which gives legal sanction to practitioners and experts alike to consider the 'health' of the mother in a very wide sense." It may be that the time is ripe for a critical restatement of such a formula.

What are the subtle archaic motives which make some of us feel so uneasy about assuaging a woman's distress by a fully warranted therapeutic abortion, as if we were doing something against our conscience?

Professor E. W. Anderson:

Study of the literature over the past thirty years shows little general agreement over the psychiatric indications for termination of pregnancy. At one extreme, some, like Bumke, believe that such indications hardly exist, at the other those like Brill would extend them widely. The majority occupy a midway position. In general medicine the indications are tangible and on the whole widely accepted. In psychiatry this is not so. The criteria of psychiatric diagnosis vary with the individual observer, notably with the diagnosis of schizophrenia. Since many writers hold that pregnancy acts adversely on the schizophrenic process diagnosis is no mere academic matter. As atypical psychoses with prominent schizophrenic features, some of them benign, others not, are frequent amongst puerperal illnesses a history of such in a previous confinement might lead to difficulty in deciding action, if the view just mentioned is accepted. Perhaps the most important factor hindering basic knowledge of the problem is the paucity of clinical material and the extreme difficulty of investigating what exists in a scientifically valid way.

Numbers of all therapeutic abortions to live births in seven leading American clinics

ranged from 1 : 35 to 1 : 16,750. In the latter series none for psychiatric reasons (Cosgrove and Carter);

84 : 25,516 (female hospital admissions over ten-year period) 6 for psychiatric reasons (7%) (Dannreuther);

1 : 500 (deliveries), 80 therapeutic abortions in twenty-year period, 1 psychiatric (1·25%) (Siegel and Kohn);

280 : 46,841 pregnant women treated over ten-year period, 9 psychiatric (3·2%) (Kuder and Finn);

Of 1,489 therapeutic abortions over ten-year period, 8 on psychiatric grounds (0·54%) (Heidler);

15 : 5,000, none psychiatric (McIlroy);

51 : 569 women referred for opinion on termination, 4 psychiatric (Gornick);

593 : 44,003 deliveries, 74 psychiatric fourteen-year period (12·5%) (St. Mary's Hospital, Manchester);

28 : 2,665 abortions, none psychiatric (Davis).

No doubt, as Fairbairn remarked, there is a big difference between the figures for private and hospital practice.

In England abortion is a felony, although the law, not as clear on this matter as it might be, tolerates it for valid medical reasons. The other indications, the social, the humanitarian and the eugenic are not recognized. A further factor hindering progress would seem to be the frequent failure to separate the medical from the social indication which in psychiatric cases is persistently obtrusive and often so closely interwoven with ætiological considerations, that its sharp divorce from the medical becomes virtually impossible. This has been widely recognized, e.g. Maier and Hart. It is not surprising therefore that data are still fragmentary and contradictory. The remarkable thing is that comparatively little has been done to study the problem systematically. Historically the literature falls into two periods, that of impressions and that of attempted systematic study. English opinion as expressed by the Royal Medico-Psychological Association in 1927 (Lord) was, on the whole, against abortion on psychiatric grounds and Robinson in 1933 elicited a similar view from 95 English psychiatrists. Hart, however, whilst doubting its value in psychoses advised greater flexibility of approach to the matter in the psychoneuroses. Kogerer (1931) referred to observations by several authors that certain schizophrenics became worse with pregnancy, but this was certainly not invariable. Boyd (1942) summed up the matter by admitting the lack of basic knowledge and hence the entire unpredictability of results of therapeutic abortion in psychiatric cases. The second period was inaugurated in Switzerland following a change in the Swiss Federal law by which abortion became permissible where continuation of pregnancy seemed likely to damage the mother's health. Only four cantons had previously recognized this. A series of important studies appeared by Binder and a number of others including Zolliker (1937–38), Glaus (1948), Maier (1932) and Schneider (1942). Binder from his series of 350 unmarried mothers sought to establish more precise psychiatric indications. He found that 7% of these women developed chronic psychiatric invalidism. He postulated two essential criteria: (1) a pre-existent abnormal psychic constitution, and (2) a degree of situational stress incapable of relief by the normal social measures. None of his normal women developed lasting mental illness whatever the stress. Interruption is not called for in every schizophrenic but only where symptoms appear for the first time at the beginning of a pregnancy or where already existent process symptoms become worse or a previous pregnancy seemed to have precipitated the illness. More recently Ekblad in Sweden has published the results of legal abortion in 479 women. This study also became possible through legislative change. 65% of these women withstood the procedure without ill-effects, but some 25% showed guilt reactions varying in severity. Siegfried found 36 such (59% in a series of 61. Polonio and Figueiredo found abortion responsible for 20% of the attacks in a series of 244 cases of puerperal psychosis. This is at variance with Vallejo Nagera's (1945) figure of less than 2% for both spontaneous and induced abortion. Polonio believes that pregnancy, far from being traumatic, actually protects against mental illness.

In the Manchester University Department of Psychiatry a study of this problem was begun in 1950. The following preliminary and provisional findings relate to 52 women, 49 pregnant and 3 not pregnant, referred for opinion on sterilization. I interviewed each patient personally, a history was obtained from the nearest relative by a psychiatric social worker and a follow-up attempted. This ranges from six months to five years. In addition each patient was given a so-called projective test by a psychologist. The women were mostly out-patients, although 9 were admitted for a time before and/or after confinement. Admission of each case, although ideal, was impracticable for various reasons. The average age of the group was 29·7 years (range 20 to 43). 5 were single, 2 widowed, 45 married. The majority, 29, were Anglican, there were 9 Roman Catholics and the remainder of other persuasions. The number of pregnancies ranged from 1 to 8. 39% were in their first or

second, and 43% in their third or fourth. The largest number (14) were in their third, 10 in their first, and 1 in her eighth pregnancy. 17 were recommended for termination, in 12 this was done. Sterilization was performed simultaneously in 5 of these. 6 pregnant women were recommended for sterilization only, which was carried out in 3. Of the 3 non-pregnant sterilization was advised and performed in 2.

Diagnostic categories comprised chiefly three groups totalling 40 patients, personality disorder 13, affective states 17 and asymptomatic 10 (including 3 women with a history of previous puerperal psychosis).

The remainder were made up as follows: Obsessional states 7; hysterical reactions 2; epilepsy with psychiatric features 2; disseminated sclerosis with psychic changes 1, and one other with disseminated sclerosis included in another category. 4 patients were considered too late for termination, although in 3 this would have been advised had they been seen earlier. 10, possibly 11, of the pregnancies were illegitimate (*c.* 22·5%). Some degree of suicidal risk, occasionally serious, existed in 23. This is at variance with Binder's findings and also with our own elsewhere in a study of young unmarried mothers. 10 attempted abortion, 1 other considered it and alleged spontaneous abortion occurred in 6 (*c.* 12%).

This compares with 29% in a similar series (Neuweiler), 17% and 17·5% respectively in two similar, larger series (Rumpf and Noell, 1950; Amstad 1934). Only the first 42 cases are considered here, the remainder have been under review for too short a time for adequate follow-up. Of the 42, in 9 follow-up was impossible. Follow-up is more than usually difficult with these women, the mentally normal when referred often leave in anger and refuse further access, many are unusually feckless and shiftless and tend, more than average patients, to drift away. Of the 11 under review whose pregnancies were terminated only one benefited conspicuously, a widow of 39 raped by a stranger. She reacted with shame and grief, could not face her adolescent children and attempted suicide. Since the latter was virtually certain if her pregnancy continued and since neither admission nor social measures would have helped, abortion was advised. In 10 others the benefits were more doubtful. In one who had had a previous, possibly schizophrenic, puerperal illness, termination may have prevented an exacerbation. 2 others showed some symptomatic improvement. In 6 no benefit was noted, while in the last 2 no further information was obtainable. Of the 5 recommended for termination, one who refused it still had symptoms of a previous puerperal illness when first seen. She went to term without mishap and two years later was well. One other, a sensitive anankast, developed a puerperal illness diagnosed elsewhere as schizophrenia and on follow-up was still sensitive and suspicious. Of the remaining 3 there is no information. Of the 32 not recommended for termination 24 are considered here. 5 attempted abortion, 1 considered it and 3 had an alleged spontaneous abortion. 12 went to term without lasting ill-effects. 6 showed little or no improvement. It is possible that termination might have helped 3 of them. In 6 follow-up was impossible.

Obviously no firm conclusions can be drawn from such a small series. In some cases of schizophrenia abortion may be advisable. There were no certain schizophrenics in this series, hence on the basis of this material I can make no personal judgment. Where suicidal risk is real the patient should be admitted. By this means several of my patients have been brought successfully to term. Sterilization was followed by striking improvement in one woman, in another associated also with termination, the opposite. In the light of this study I would strongly advise against termination or sterilization in women with strong anankastic and depressive features since either is likely to be followed by severe self-reproach, of which 4 instances were found in this series. Severe economic and marital stress existed for 12 women. I believe we tend to underestimate considerably the capacity of woman to withstand stress. Nevertheless, if the State insists on a woman bearing her child, the State must ensure more adequate social services, in particular more trained social workers, than exist at present. I believe that thereby fewer therapeutic abortions on psychiatric grounds would be necessary. If I have gained one impression from this study, it is that abortion in the large majority of psychiatric cases has very little medical justification.

Professor W. C. W. Nixon:

It would appear from the legal aspect that the onus is on the operator—the gynæcologist—to justify his action of termination of pregnancy. It is he who does the operation, not the psychiatrist. It is he who carries the full responsibility for acting in good faith. Good faith are the operative words. The general surgeon or the physician rarely has to carry a responsibility of such gravity. Who can blame my colleagues who shrink from exposing themselves to such an exacting test—moral cowardice is a question of degree? Yet there are women whose pregnancies should be terminated on justifiable grounds but in whom an abortion is not done because the gynæcologist is fearful of being dubbed an abortionist. This situation arises especially in small provincial, as distinct from teaching, hospitals.

The threat of suicide is one which I, as a gynæcologist, find difficult to assess but it is possible to under-estimate the gravity of this threat. If a patient does not gain relief from an interview with a gynæcologist or psychiatrist then she may do something drastic. If we still subscribe to the Hippocratic oath then it is the duty of doctors to prevent patients injuring themselves. If we are convinced an injury is going to happen then we must act. Suicide is a destructive act against society. Apart from the complete destruction of the individual there are varying degrees of injury, either physical or psychological. We must therefore, accept a broad connotation of health if society is to be protected from the loss of properly functioning individuals and if we are to prevent such persons becoming permanent invalids.

There are those who consider that the only valid indication for termination of pregnancy is when there is also an indication for sterilization. I think vindictiveness of this kind is a form of blackmail which should have no place in gynæcological practice.

I cannot deny that some psychiatrists have gained the reputation of being "abortion easy" and that patients are misled in the belief that termination can easily be obtained on psychiatric grounds. Perhaps it is for this reason that some gynæcologists resent being requested on psychiatric grounds to terminate pregnancy and, therefore, adopt an obdurate and contrary attitude. There is also the impression that we are being employed solely as mechanics. Yet I fail to see how any gynæcologist, unless he has made a special study of psychopathology, can question the opinion of a reputable psychologist. The operative word is "reputable". There are "consultoids" in every medical specialty and if I am to be used merely as a surgical technician then I will be directed only by those whose opinion I respect and who I know act in good faith.

In view of the stand that many gynæcologists take against the advice of psychiatrists—a stand which is essentially protective, it has been suggested that the way out of the impasse psychiatrist *v.* gynæcologist is the establishment of Abortion Panels. By such a system any imputation that abortions were done on flimsy indications could be countered. Such a panel was instituted ten years ago by Mr. Philip Mitchell, senior gynæcologist at the Royal Hampshire County Hospital at Winchester.

Just as a surgeon follows up all cases on which he has operated so should a psychiatrist continue to supervise the care of all women who have had a termination. If the psychiatric indication for this operation is made urgent then I see no reason why with the termination of pregnancy the psychiatrist should cease to be interested in the woman's future. Does the evacuation of the uterus cause an immediate amelioration of the psychosis? I venture to

suggest that psychiatric care should be an important part of the rehabilitation that a woman needs after this operation. We are all aware how some patients deeply regret this operation and develop a severe depression.

It is asking a lot of the gynæcologist to repeat the operation a year later and those who have the psychiatric responsibility for these patients must arrange for proper contraceptive advice or alternatively seriously consider the advisability of sterilization.

During the years 1938–1956 (inclusive) there were 509 cases of termination of pregnancy at University College Obstetric Hospital. Of these 198 (38·9%) were for psychiatric indications.

This is not the time to describe surgical techniques for termination of pregnancy. I prefer vaginal hysterotomy; it is possible to sterilize at the same time provided the gestation is not greater than twelve weeks. I find I am supported in this method by my colleagues in Sweden who have had far greater experience than I. The real problem is when the pregnancy is so advanced in the second trimester that an abdominal hysterotomy is necessary. This operation is really a Cæsarean section in miniature and the fœtus may survive apart from the mother. I do not think any gynæcologist should be asked to terminate at such a late stage and the onus should be placed fair and square on the psychiatrist to continue treatment of the patient in an institution.

Of all gynæcological operations that of therapeutic abortion is the one that causes me most discomfort. Not only is there the destruction of the fœtus—one can feel the shudder of the theatre staff—but also the inherent risk of uncontrollable hæmorrhage. There is the constant vision of the coroner's court—deaths do occur.

The *immediate* operative risks are those of hæmorrhage, perforation or sepsis, the *remote* are sterility and habitual abortion due to laceration of the cervix. Perhaps the sudden evacuation of the uterus may lead to "endocrine shock" which may later influence menstruation (dysmenorrhœa, menorrhagia), ovulation, or even the personality of the individual.

Mr. Aleck Bourne said that abortion is useless for treatment of an established psychosis complicated by pregnancy. After the third month vaginal abortion becomes an increasingly dangerous operation as time passes, and, when performed for a mental condition short of psychosis, is often followed by remorse which will aggravate the patient's neurosis, perhaps for years.

Abortion for any mental illness is seldom necessary, for the majority of patients become reconciled to the prospect of having a baby, after the middle of pregnancy. Suicide is often insincerely threatened as a kind of blackmail, but if, in the opinion of a psychiatrist, suicide is a genuine danger pregnancy should be terminated. As abortion cannot be repeated, and as contraception is unreliable in the hands of many of these patients, it is occasionally necessary, where the mental condition is regarded as permanent during the childbearing period, to sterilize at the time of hysterotomy.

Dr. Eustace Chesser:

It seems that the psychiatrists are not familiar with the usual psychological factors justifying termination of pregnancy. Greater reliance should be given to the general practitioner's opinion with his unique knowledge of the patient and her background.

Mr. Aleck Bourne suggests that sterilization should always accompany termination; why? To say "you should not have a child" is a far cry from "you cannot have a child". The mentally-sick patient of to-day may well be the mentally-healthy patient of to-morrow.

Dr. Noel G. Harris:

Occasionally a request is made to terminate a pregnancy not for the sake of the mother, but for the sake of the father. A recent example of that was seen with a woman married to a man who had had psychiatric treatment and was thought to be not far off a schizophrenic breakdown when her first pregnancy began. The father was distressed at the idea of the added responsibility of a child. His wife became anxious and distressed at the attitude her husband adopted in case it precipitated a complete breakdown in him. The psychiatrist who had treated the man thought the pregnancy should be terminated.

It is not uncommon to find that women who are sent up for termination of pregnancy have had no education or advice on birth control. Psychiatrists, obstetricians and general practitioners should see that married couples get adequate knowledge and instruction on this when they want it.

Dr. G. F. Abercrombie said that few general practitioners saw enough of these patients to form an opinion, but that he himself was becoming increasingly convinced that termination of pregnancy on psychiatric grounds was not the right answer.

Section of Pædiatrics

President—D. V. HUBBLE, M.D., F.R.C.P.

[*November* 23, 1956]

Congenital Agranulocytosis.—J. R. K. HENRY, M.B., D.C.H. (for J. P. M. TIZARD, M.R.C.P.).

Girl, aged 6 months. Admitted to hospital on 16.5.56 aged 16 days. She was the first baby, born at home after a normal pregnancy and delivery. Both parents were healthy.

Two days before admission there was a thin watery discharge from the left ear, and the day before admission she developed a profuse but clear nasal discharge, which interfered with her feeding. There were some small glands in the posterior triangles of the neck.

On the day before admission she had had two doses of 2·5 ml. of Cremotresamide (total of 0·2 gram sulphadiazine, 0·2 gram sulphacetamide and 0·1 gram sulphamerazine). Blood count on admission: Hb 16·3 grams%, W.B.C. 7,000/c.mm. Eosinophils 23% 1,610/c.mm. Lymphocytes 68% 4,760/c.mm. Monocytes 6% 420/c.mm. Türk cells 3% 210/c.mm.

A bone-marrow examination two days later showed erythropoiesis to be proceeding normally. Granulopoiesis was abnormal, the striking feature being the complete absence of neutrophil myelocytes, metamyelocytes and polymorphs, though eosinophils and basophils were present and developing normally. There was a slight excess of blasts. Megakaryocytes were present in normal numbers.

A nasal swab, throat swab and swab from the left ear grew *Staphylococcus pyogenes* which was sensitive to penicillin. Plasma proteins and electrophoretic pattern were normal.

She was treated with penicillin and made some improvement. Two weeks later she developed an abscess in the left cervical region, probably as a result of withdrawing blood from the external jugular vein. The organism cultured from these lesions was again a *Staphylococcus pyogenes* which was now resistant to penicillin.

She has had a further four admissions for septic skin lesions, tonsillitis and otitis media. Repeated examinations of her peripheral blood have shown a constant absence of neutrophils with a normal number of lymphocytes and a raised eosinophil count.

An interesting feature was that examination of her plasma proteins showed a gradual reversal of the A/G ratio, with a marked increase in the gamma globulin. The patient was given cystine 0·5 gram t.d.s. by mouth for two weeks with no alteration in the white cell count (*see* Kostmann, R. (1956) *Acta pædiat. Stockh.*, Suppl. 105).

Discussion.—If the very small dose of sulphonamides given on the day before admission can be ignored, it seems reasonable to consider this as a case of congenital agranulocytosis and similar to those described by Kostmann and considered by him to be inherited recessively.

It seems probable that this is a rare disease which, in the past, may have hidden under names such as pemphigus and cancrum oris, and has only come to light with the advent of antibiotics. These, although not altering the final prognosis, may prolong life for several years.

POSTSCRIPT.—The patient died on 17.1.57.

Obstructive Jaundice and Sepsis Following Exchange Transfusion for Group B Incompatibility.—LESLIE G. ANDREWS, M.B., D.C.H. (for J. P. M. TIZARD, M.R.C.P.).

Girl, aged 4 months. Born July 27, 1956. She became jaundiced within twenty-four hours of birth due to Group B incompatibility. She was severely affected and in all, three exchange transfusions were performed, through the umbilical vein. The serum bilirubin at its highest was 35·2 mg./100 ml., most of the pigment being of the indirect reacting type. No signs of kernicterus developed. Prophylactic antibiotic therapy was given following the second exchange transfusion.

Moderate jaundice persisted. On the 10th day of life the child became acutely ill, and had hepatosplenomegaly, veins coursing from the abdomen to the chest, ascites and some leg œdema. She was thought to have developed either a cholangitis or abscesses in the liver. The ascitic fluid grew *Staphylococcus pyogenes* resistant to the antibiotic used. At the same time the jaundice increased and the stools became pale. The serum bilirubin was now mainly of the direct reacting type of pigment, the child having developed an obstructive jaundice.

The infection gradually abated with a change in antibiotic therapy, but on the 52nd day of life she suddenly developed an acute intestinal obstruction. Laparotomy revealed a low grade peritonitis with pooling of the fibrinous exudate in the hepatic flexure, causing a paralytic ileus in this region. Further staphylococci were grown from the peritoneal exudate and from a blood culture. Following intravenous drip therapy and gastric suction and a further six weeks of antibiotics the ileus and obstructive jaundice gradually resolved.

The sequence of events seems to have been—Severe Group B incompatibility necessitating

three exchanges, following which the patient developed a pyelophlebitis and possibly a portal vein thrombosis. A peritonitis also occurred and gave rise to the paralytic ileus. There was an associated obstructive jaundice.

Discussion.—Group B incompatibility is seldom severe enough to necessitate three exchanges. Obstructive jaundice associated with hæmolytic disease of the newborn is not uncommon and is usually due to inspissated bile obstructing the intra- and extra-hepatic ducts. Sepsis following umbilical exchange transfusion seems to be very rare with only two other reports of it in the literature, although many more cases may occur.

Diastematomyelia.—J. P. M. TIZARD, M.R.C.P.

Girl, aged 3 years 6 months, was noticed at birth to have a tuft of long, fine hair overlying the mid-dorsal spine. X-rays displayed a picture interpreted as diastematomyelia. The 5th to 9th dorsal vertebræ and the spinal cord are widened; the disc spaces are narrowed and there is a vertical median bar of bone starting at the 5th vertebral body and extending downwards to the upper border of the 7th.

No operative treatment has been carried out and the child has at no time shown any defect of locomotion or of bladder control and there are no abnormal neurological signs.

Discussion.—The spinal column grows faster than the spinal cord and the development of neurological defect in cases of diastematomyolia is attributed to the increasing pressure exerted on the cord by the bony spine transfixing it. Most modern writers on this subject regard spinal cord damage as being sooner or later inevitable and therefore advocate early operation. For instance, Matson and his colleagues (1950) state that it is "good preventive medicine to carry out surgical treatment of diastematomyelia associated with spina bifida occulta at any time the diagnosis is made in early infancy and childhood". In most cases of diastematomyelia, however, the defect is found in the lumbar or lower thoracic region. Of 22 cases reported by Ingraham and Matson (1954) in only one was the defect above the level of T.8. It is obvious that the higher up the cord, the less is the difference in growth rate between cord and spine and it is suggested that a conservative policy may be justifiable in this case. The decision not to operate early was made in collaboration with Mr. Valentine Logue and the child has been, and will continue to be, re-examined at regular intervals.

Brachial Plexus Palsy Associated with Soft Tissue Atrophy in the Scapular Region.—J. P. M. TIZARD, M.R.C.P.

Girl, aged 15 months. Pregnancy normal; uneventful vertex delivery. She was noticed at birth to have the following abnormalities: (1) Weakness of the left arm, due apparently to an upper trunk brachial plexus palsy (Erb-Duchenne type). (2) Various skin lesions: (*a*) About a dozen small (2–3 mm. diameter) faintly bluish shallow pits, mainly on the left side—limbs, trunk and upper lip; (*b*) two vascular nævi, one on each thigh; (*c*) an ill-defined, irregular patch of atrophic skin (4×3 cm.) attached to subcutaneous tissue above the left scapula.

The vascular nævi have now started to regress and the other skin lesions, although still present, are inconspicuous. There has been little or no improvement in the paralysis of the left arm. No abduction of the arm, nor supination of the forearm seems possible. There is some ability to flex the forearm. Hand movements are unaffected. There is wasting of the left deltoid and upper arm muscles and absence of the left biceps and supinator jerks. There is no obvious loss of pin-prick sensation. There is no sign of an upper motor neurone lesion in the legs to indicate cord damage and no evidence of sympathetic chain involvement (Horner's syndrome) to suggest root damage.

Discussion.—The prognosis in cases of birth palsy of the upper brachial plexus type is generally considered to be good, although recovery is by no means invariable. On the other hand, it is very unusual for the delivery of a baby with brachial palsy to have been entirely normal (Morison, 1938). It is suggested that the palsy of the left arm in this child was not due to stretching or other damage to the brachial plexus at birth, but to prenatal malformation associated with a similar process in the overlying subcutaneous tissue and skin.

REFERENCE.—MORISON, J. E. (1938) *Arch. Dis. Childh.*, **13**, 310.

Acrogeria.—DAVID MORRIS, M.R.C.P.

Girl, born January 23, 1950. Both parents are healthy and there is no history of consanguinity. The pregnancy and the delivery were normal but the child was born prematurely without obvious cause; the birth-weight was 4 lb. 12 oz. Elder female sibling is alive and well and normal. A second sibling died in 1948 from tuberculous meningitis, no contact was found.

Progress had been normal from birth till 3½ years of age when she developed a tendency

to bruise easily and the parents became concerned over her "poor general condition". Blood examination, including bleeding and clotting times, was normal. The child appeared to lack subcutaneous fat over the whole body but particularly of the hands and feet (Figs. 1, 2, 3). These were emaciated and fleshless with the veins showing through the

FIG. 1.

FIG. 2.

FIG. 3.

thin and wrinkled skin similar in appearance to the hands and feet of old people. The descriptive label of peripheral ectodermal dysplasia was given at the time. Three years later Dr. G. B. Dowling identified the condition as acrogeria as described by Gottron (1940). Only two other reports of the condition could be traced in the literature, Gromzig (1951) and Bazex and Dupré (1955). There do not appear to be any other associated anomalies.

Periodic Neutropenia—A Family Study.—T. J. PARKINSON, M.R.C.P., and B. W. MEADE, M.D. (for MARY J. WILMERS, M.D.).

Girl, aged 10 months when first seen with an ulcer on her lip which had failed to respond to local treatment (Fig. 1). A blood count showed hæmoglobin 8·9 grams/100 ml., total white cells 2,800 per c.mm., neutrophils 980 per c.mm. Three days later the neutrophils were 80 per c.mm. A diagnosis of agranulocytic angina was made and treatment instituted with antibiotics, Pentnucleotide, folic acid and a transfusion of fresh blood. Marrow biopsy showed maturation arrest of the myelocytic series. Gradually her condition improved and her neutrophil count rose to 8,260 per c.mm.

She remained well for almost a year, but then suffered another attack with ulceration of her mouth and vulva. Her neutrophil count fell to 777 per c.mm. Again she recovered with antibiotics and her neutrophil count rose to 6,120 per c.mm.

From then until the age of 7 the ulceration recurred, accompanied by malaise and variable pyrexia. At this time the diagnosis of periodic neutropenia was made on the basis of repeated blood counts. A typical cycle is shown diagrammatically in Fig. 2.

Other members of her family have had similar recurrent ulceration. Her father has been observed with ulcers and concomitant with one crop a neutrophil count of 1,312 per c.mm. was obtained. At other times his blood count has been normal.

Her aunt also has recurrent mouth ulcers. Two counts have been made which showed neutrophils at 2,000 per c.mm. and 2,280 per c.mm. respectively. Her grandfather has suffered from mouth ulcers but the only blood count recorded is normal, and we have been unable to study him during an attack.

Comment.—This child presents the clinical features and blood count of periodic neutropenia as described by Rutledge *et al.* (1930), Borne (1949), Embleton (1937), Barling (1948), Vahlquist (1946) and Moncrieff (1951). Her father presents a similar, though less well-documented picture, with attacks of mouth ulcers associated with neutropenia. Her aunt and grandfather appear to have the same condition.

The occurrence of this rare condition in more than one generation of a family does not appear to have been reported before.

FIG. 1.—Showing an ulcer seen in the first agranulocytic episode. Both the child and her father have recurrent crops of ulcers of this type.

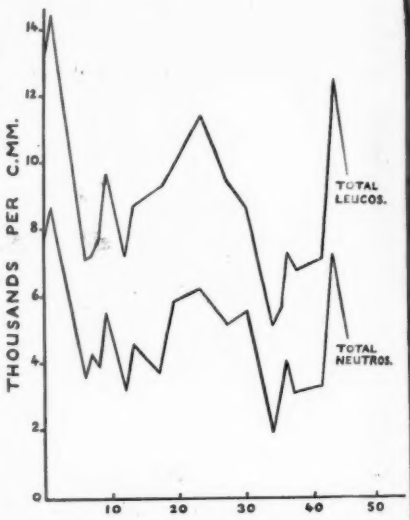

FIG. 2.—Showing neutrophil and total leucocyte counts, recorded for a seven-week period at the age of 7 years.

Letterer-Siwe Disease Treated With Prednisone.—EVA A. FROMMER, M.B., B.S., D.C.H. (for W. MESTITZ, M.D.)

Girl, born 4.2.56, is the only child of healthy parents. The delivery was normal, at full term, birth weight 7 lb. 13 oz. and she was breast-fed. She was first seen at the skin clinic of the Royal Alexandra Hospital for Sick Children, Brighton, in March 1956, at the age of 7 weeks, with a rash of four weeks' duration. This failed to respond to treatment. About two months later a chest X-ray was taken, as the baby was seen to be cyanosed. The film showed widespread mottled infiltrations of both lungfields, with a suggestion of honeycombing particularly in the lateral view. The baby was referred to Dr. W. Mestitz who admitted her for investigation. She was now aged 5 months, had been weaned, but was not thriving as well as formerly. She had recently been coughing.

Weight was 12 lb. ½ oz., Temperature 98·8° F., pulse 130 and respirations 35 per minute. She was an ill-looking, snuffly baby; a rash of brownish-yellow, crusted papules and petechiæ covered the trunk and groins. High-pitched tubular breathing was heard over the base of the left lung posteriorly. The liver was just palpable, and the spleen enlarged to two finger-breadths below the costal margin, and hard. A few glands were felt in both groins.

The diagnosis of Letterer-Siwe disease was suggested, and confirmed by the biopsy of a wedge of skin, with several flat-topped papules (Fig. 1 A and B).

Histology.—The lesions are confined to the upper dermis. Each papule is formed by œdema and cellular infiltration of a group of papillæ; where this occurs the epidermis becomes thinned, the dermo-epidermal border becomes blurred, and there is "rat-tailing" of the rete partitions in a manner reminiscent of lichen planus. The infiltrate is composed mainly of large reticulum cells with a foamy cytoplasm; there are also neutrophil and eosinophil leucocytes and small lymphocytes; the latter types of cell tend to infiltrate the epidermis, as well as the dermis. It has not been possible to demonstrate whether or not lipoid is present in the reticulum cells, but even without this information, the presence of such cells as a major constituent of the infiltrate places this lesion in the Letterer-Siwe group of lipidoses.

Further investigations.—Hb 93%, white cell count within normal limits, platelets 22[illegible]000;

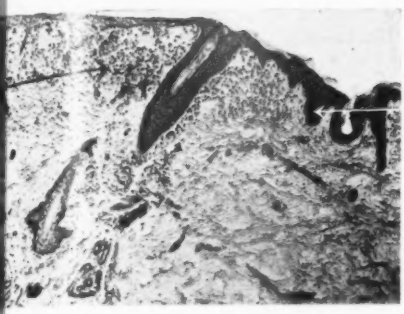

FIG. 1A.—Low-power view of the skin biopsy showing normal skin, a, and an area of infiltration, b.

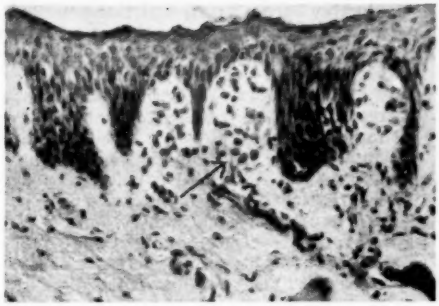

FIG. 1B.—High-power view of the area b, above, illustrating the character of the infiltrate. The arrow points to a group of histiocytes with foamy cytoplasm.

bleeding time 4½ min., clotting time 4 min. 10 sec. Blood cholesterol 250 mg.%, serum proteins 5·8 grams%, A/G ratio 2·4 : 1. X-rays of skull and skeleton: no abnormality.

Treatment with prednisone was commenced on 17.8.56, 2·5 mg. six-hourly. As the skin condition did not improve and the lung picture deteriorated the dose was doubled one month later. Following this there has been steady improvement, with quick resolution of the lung infiltrations, and gradual fading of the rash.

There have been several pyrexial episodes due to minor staphylococcal skin infections, which have responded to antibiotics. The child is thriving, and progressing normally. Some fullness of the face, and a double chin have developed recently, and the dose of prednisone was reduced to 5 mg. thrice daily; however, during a recent severe upper respiratory infection the rash became more marked, and there was some enlargement of the spleen; the dose was therefore increased to 7·5 mg. thrice daily, with beneficial results so far.

Comment.—It is now generally recognized that Letterer-Siwe disease, or infective reticuloendotheliosis, is closely related to Hand-Schüller-Christian syndrome (and eosinophil granuloma of bone), as pointed out by Wallgren (1940). It appears to be the form of the disease which manifests itself in infancy and early childhood. At this age it is more malignant, with a very poor prognosis, although occasionally spontaneous recovery has been reported.

Antibiotics have been tried, with moderate success, as have X-ray treatment and nitrogen mustard. The latest addition in the therapy of the disease is cortisone, and ACTH. Cox (1953) has described a case treated successfully with cortisone, and has reviewed this form of treatment (1955–56).

Our patient is being treated with prednisone, and we believe that her improvement is *propter hoc* and not *post hoc*. She was very ill on admission, and continued to deteriorate until treatment was begun. She improved soon after the dose was increased, with quick resolution of the pulmonary lesions. The rash is proving more obstinate, and the spleen slow to diminish in size. A similar progression of events was noted by Cox in his case; the last relapse shows that the scheme of treatment must be flexible, and the literature suggests that, on the whole, a high dosage is required and that the treatment must be maintained over a long period. We propose to reduce the dose slowly, guided by the clinical findings, and to discontinue it eventually if this proves possible.

We are indebted to Dr. R. I. K. Elliott for the section report, and photographs.

POSTSCRIPT.—The baby subsequently deteriorated quite rapidly and in spite of increasing doses of prednisone she had several successive cyanotic attacks necessitating continuous oxygen therapy and died on March 12, 1957.—E. F.

Multiple Congenital Nerve Palsies.—CLIVE UPJOHN, M.D. (for J. N. O'REILLY, D.M.).

Boy aged 15 months. *History.*—Mother gravida 1. Pregnancy normal and full-term. Long first-stage labour lasting nearly 41 hours, when she was an emergency admission to another maternity hospital. On admission there, mother's cervix was only 3 fingers dilated and when full dilatation had occurred birth was assisted with a low forceps delivery.

Baby's condition at birth poor with blue asphyxia. Colour remained poor initially but responded to intranasal oxygen after a few hours. Birth weight 7 lb. 14 oz. He was very

"bubbly" from birth, and this persisted despite frequent extraction of mucus. Cyanotic attack developed at the onset of first bottle feed. Œsophageal atresia was excluded by passage of a catheter into the stomach. He remained bubbly and was transferred to St. Helier Hospital at 14 days of age.

On admission.—General condition satisfactory. Left facial paralysis, probably upper motor neurone type. Recurrent attacks of laryngeal obstruction occurred as a result of rapid collection of saliva and mucus in the nasopharynx. Lipiodol introduced into the nasopharynx was promptly aspirated into the trachea, giving a generalized bilateral bronchogram. A neuromuscular defect was suspected and he was seen by Mr. L. F. W. Salmon, E.N.T. specialist, who confirmed that the baby had a right palatal and pharyngeal paralysis, and direct endoscopy showed paralysis of the right vocal cord.

Progress.—Up to 3 months of age mucus and saliva continued to collect rapidly, causing frequent recurrence of respiratory obstruction requiring aspiration every five to ten minutes. After this time aspiration was required less frequently, varying from twenty minutes or longer, up to 6/12 of age, when there was a marked improvement, but aspiration was still required four-hourly before feeds until 8/12 of age.

All feeds were given by tube up to this age, when it became possible for him to take increasing amounts from a spoon; clear sterile fluids were given initially but he progressed quickly to milk and semi-solids by 9/12 of age. His subsequent progress was satisfactory and he was discharged home aged 11/12, weighing 23¾ lb.

His development is normal and he is a robust and very active child.

His condition was reviewed at 15/12 of age. Right pharyngeal paralysis persists. He weighed 28 lb. He swallows semi-solids most easily. He still chokes at times on liquids, and he has difficulty in swallowing any dry or solid food. Walking and talking well advanced.

Comment.—Initially this child's clinical condition was strongly suggestive of œsophageal atresia. After this had been excluded the alternative diagnoses were: (1) Neuromuscular abnormalities. (2) Tracheo-œsophageal fistula. (3) Sabre-defect in posterior laryngeal wall.

Investigation showed the presence of multiple cranial nerve palsies and it has not been possible to decide whether these were due to birth trauma or congenital failure of development. After this diagnosis the management became predominantly a nursing problem requiring constant attention for many weeks.

Peripheral Dysostosis.—S. D. V. WELLER, M.D., M.R.C.P.

Male, aged 15 years. Elder child of healthy parents. Father below average height, having short feet with high arches, but neither parent shows signs of peripheral dysostosis, and sister is also normal. No significant past illnesses, but wore arch supports between ages 5 to 10 years.

FIG. 1.

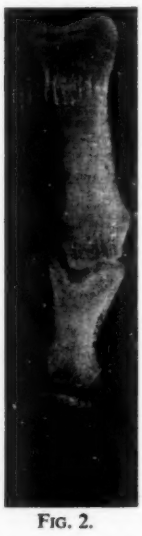

FIG. 2.

Presented in May 1953 with complaint of fingers becoming misshapen for five months. Deformity had been painless except during rubella in March 1953.

On examination (aged 11½ years).—Rather adult facies. Spindle swelling of fingers with some deviation, particularly at first interphalangeal joints. Short great toes. Negligible disability.

X-rays.—Conical epiphyses showing irregular central fusion, with metaphysis tending to grow over the lateral epiphyseal margins. This feature most obvious in proximal phalanges of great toes and middle phalanges of fingers. Dense epiphyses on some distal phalanges (a normal variant) (Fig. 1).

Progress.—Deformity has progressed painlessly

Present state.—All epiphyses fused in hands and feet (Fig. 2). Those previously normal have fused normally, as have those that were unduly dense. Abnormal epiphyses have fused, but look almost as if they have been absorbed into the cup which the metaphysis had previously formed about them. This has led to some obliquity at the interphalangeal joint.

FIG. 1.—X-ray of left middle finger; condition on 7.8.54.

FIG. 2.—Condition on 20.11.56.

Partial fusion has occurred at the knee epiphyses. All epiphyses are fusing prematurely and the patient has apparently stopped growing.

DISCUSSION ON THE MANAGEMENT OF PATIENTS SUFFERING FROM PULMONARY TUBERCULOSIS

Dr. A. Brian Taylor: The aims of treatment of pulmonary tuberculosis were given by Livingstone (1955) as follows: (1) Permanent healing of the lesion; (2) Minimal loss of respiratory function; and (3) The attainment of these in the shortest time.

The indications for treatment and methods to be used are more controversial. Burrell (1930) in his Mitchell Lecture described mainly clinical evidences of activity. Nowadays radiological appearances have largely, perhaps excessively, superseded these. At the same time, morbid and histological characters, particularly of resected lesions, have influenced many towards a more aggressive and radical attitude, though the experience of the past has shown that tuberculosis can heal and may do so permanently in situ. The patient himself, with his personal problems, loses something of his importance. For instance, restoration of health is nowadays largely, though inadequately, defined as restoration of the ability to work—a reflection of the modern Welfare State. The length of treatment, especially of restriction of activity, becomes longer and longer, and at the same time intolerable.

It is necessary to plan the treatment to attain permanent healing at the first attempt. Second and subsequent periods of treatment are demoralizing and make return to useful work more difficult for the patient and his employers. The possibility of relapse has a strong influence on treatment, especially the prolongation of chemotherapy and the indications for surgery.

Early acute disease is, naturally, the most hopeful for treatment. Astonishing radiological clearing of the lungs can occur. Such complications as tuberculous laryngitis and tuberculous enteritis have almost disappeared.

Medlar (1955) divided the parenchymal disease into the non-necrotic and necrotic components. The former consists of a lobular pneumonia which can heal completely by resolution or by the formation of epithelioid tubercles which in time may heal by scar formation. This is the type of disease most responsive to the general care of the patient and the adequate administration of potent antibiotics.

Auerbach (1955) has suggested that compared with untreated disease, lesions after chemotherapy show rapid clearance of the perifocal reaction, with a thinner capsule, thinner walls of cavities and decreased pulmonary fibrosis and emphysema. This conforms to the notable clearing which can occur radiologically after early and intensive treatment with specific drugs.

In the necrotic component dissemination and cavity formation may ensue. The bacilli are particularly found in the necrotic material and may persist indefinitely and lead to relapse. Structural changes occur in the lung and cavity formation is notoriously difficult to heal. These give the chief need for additional surgical measures.

The frequent discovery of completely healed asymptomatic lesions by routine X-ray shows the common occurrence of the former process but when the lesions are of any size, their age and potential danger, by harbouring necrotic material with viable bacilli liable to dissemination, are difficult to assess. There is also the difficulty of distinguishing these lesions radiologically from the not uncommon pyocele secondary to bronchial tuberculosis (Clegg, 1953).

These latter lesions are obviously in a different category from the point of view of their persistence and danger as well as their lack of response to chemotherapy. Excision when feasible is especially attractive.

Two further considerations arise in connexion with drug treatment. One is the possibility of dispensing with prolonged and complete bed rest. An ill and toxæmic patient is obviously best in bed. An infectious patient is more easily restrained by restriction to bed. When, however, the acute stage is passed, toxæmia is absent, sedimentation rate normal, and symptoms relieved, how much rest is required? The possibility of treating indolent or recovering and favourable cases by long-continued drugs and slight modification only of normal life must be considered when risks of infection can be excluded. For the housewife, for instance, without whom the home can hardly be run, and for the University student there seem to be considerable advantages. The routine examination of Birmingham

University undergraduates at the start of each session reveals a few asymptomatic cases, apparently on the borderline of activity. To stop them working inevitably loses them a year in time, as they must wait for the next session if they are interrupted by more than a few weeks. This disorganizes them as well as the economic use of the limited places in the University. It seems possible that modification of working hours, avoiding violent exercise and chemotherapy, with close frequent supervision may be a reasonably safe compromise. Springett (1956) has shown that many minimal lesions do not relapse during simple observation and continued work. Black and Poole (1955) observed a number of round foci and found them stable and largely harmless.

The increasing tendency to continue a course of antibiotic drugs for at least a year after clinical quiescence seems most reasonable. When special hazards predispose to relapse more drugs may well be worth while. Respiratory infection and bronchitis are so commonly found immediately preceding a relapse that the winter months may be partly safeguarded by taking drugs if the urban life of a patient makes these dangers likely.

Surgery for pulmonary tuberculosis is mainly indicated for extensive structural changes in the lung, especially when cavities persist, and for nodular lesions.

Resection is most applicable for solid lesions, particularly more than 1 cm. in diameter such as result from the cold abscess (or pyocele), and if containing necrotic material with viable bacilli as described by Medlar (1955). They must be single or relatively few, and are more hazardous in unco-operative or stupid patients. Radiological appearances should not be an enticement to unnecessary surgery and removing healed safe lesions is not only pointless but may be dangerous. The disease can heal and extensive bilateral disease beyond the scope of resection often has to demonstrate this. Completely healed lesions removed and proved by histology to have been harmless are not infrequently found, and should be a reproach to the choice of surgery.

Chronic persistent thick-walled cavities, especially without much disease elsewhere and especially in the lower lobes, are as well resected.

Destroyed lungs, tuberculous bronchiectasis, localized atelectasis and chronic tuberculous pyopneumothorax are better removed.

The failed thoracoplasty, that is failure to obliterate a cavity or secure sputum conversion, is an indication for resection.

Early lesions, especially if small, localized and active, may be removed to shorten the patient's treatment instead of waiting for complete quiescence and the so-called "target point". Intensive antibiotics, of course, accompany and follow the operation.

Thoracoplasty in its various modifications has now been shown to be an effective and safe operation, leaving little functional disability and negligible deformity. Conversion of sputum occurs in a high proportion of cases, e.g. 80% of unselected cases reported by McHale (1949). In particular, it assists natural healing in situ while medical treatment continues and it can combat more extensive disease in the same lung or in the opposite lung. In fact, improvement of contralateral disease may follow collapse of the major lesion.

Mr. W. P. Cleland: *Surgical Management of Pulmonary Tuberculosis*

My remarks will be confined to patients with pulmonary and bronchial disease. I will consider these aspects under three headings, viz.:

I. The indications for surgical treatment.
II. The scope of the investigations required when planning surgical treatment.
III. The type of surgery to be employed.

I. Indications for Surgical Treatment

These may be considered under the following headings:

(*a*) *Failure of the medical regime.*—In the initial stages of treatment one is not justified in withholding any reasonable therapeutic measure. This implies the administration of full doses of the antibiotics combined with bed rest. I see little point in employing intermittent streptomycin during the initial period of treatment and would much prefer that the patient should have daily streptomycin with both PAS and isoniazid until the sensitivities

have been determined. A period of between four and six months is generally accepted by the majority as sufficiently long to expect a good response to treatment. One can define, therefore, failure of the medical regime as the persistence of tubercle bacilli in the sputum and the presence of cavitation after four to six months of bed rest and adequate chemotherapy.

(*b*) *Early drug resistance.*—The occurrence of organisms resistant to one or more drugs on the first examination is increasing. Sterilization of lesions with prolonged chemotherapy is less likely to occur when the bacilli are resistant. These patients thus present a difficult problem. Owing to the likelihood of resistance to the remaining drugs developing, surgical treatment, if indicated, is often advisable at a relatively early stage in order to have the benefits of an antibiotic cover for the operation.

(*c*) *Residual lesions or sequelæ which are considered likely to give rise to trouble in the future.*—It is this group which arouses the greatest controversy, particularly since the widespread practice of resection. It is in this group also that the benefits of long-term chemotherapy are now being claimed. Residual lesions can be considered under a number of headings:

(i) *Residual nodules.* These, if large, and particularly when solitary (tuberculoma), do not present any real problem. The larger nodules are more likely to break down and less likely to heal firmly by fibrosis than the smaller foci. It is also sometimes difficult to be quite certain about the diagnosis in such cases. Smaller nodules present a more difficult problem, and each individual surgeon and physician has his own criteria for their removal. With the pathological and bacteriological investigations of surgical specimens being undertaken, it is hoped that a clearer idea of the indications for removal in relation to long-term chemotherapy will be forthcoming. Stewart *et al.* (1956), for instance, have shown that chemotherapy can sterilize both cavities and caseous foci irrespective of their size provided the organisms are sensitive to the drugs and at least twelve months' treatment is given.

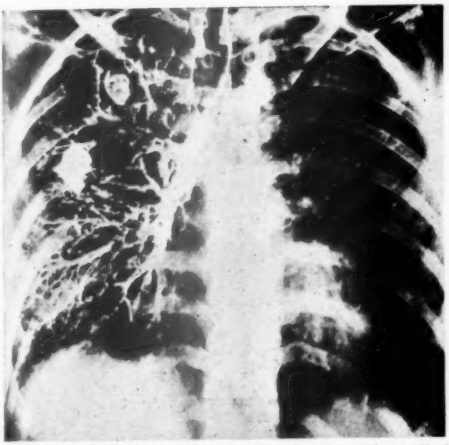

FIG. 1.—Right bronchogram showing two thin-walled cyst-like residual cavities filled with opaque oil. These cavities were not visible on the plain radiograph.

(ii) *Residual cysts.* Large, thin-walled cyst-like cavities are now appearing fairly commonly as a result of long-term chemotherapy. A number of these cysts fill readily with Lipiodol whilst others show no obvious bronchial drainage (Fig. 1). Keers *et al.* (1956) have indicated that, even after fairly prolonged periods of chemotherapy (up to fourteen months), complete histological healing may not occur and foci of tuberculous disease in the wall of the cyst can be found if an adequate search is made. Further evidence is required in such cases in order to guide one regarding their removal.

(iii) *Destroyed lobes.* The shrunken bronchiectatic and fibrotic lobe or lung following severe destructive lesions is often secondarily infected and a source of ill-health, and there is little doubt as to the necessity of its removal should conditions permit. The improvement in the patient's general condition, the elimination of cough and sputum and the cessation of hæmoptyses is most gratifying. The reduction in the respiratory reserve is negligible in these patients.

(iv) *Bronchiectasis.* The presence of bronchiectasis in an otherwise aerated lobe constitutes a more difficult problem. I think it is important to distinguish between the relatively minor bronchial dilatations occurring peripherally in relationship to a tuberculous focus and the grosser forms of bronchiectasis involving the whole of a lobar or segmental bronchus.

It is this latter group which we are considering here. In the lower lobe, these lesions are frequently secondarily infected and there is often a clear-cut indication for their removal. Similar lobar bronchiectasis involving the upper lobes is less likely to give rise to symptoms. Its presence, *per se*, does not constitute an indication for removal but these lesions sometimes

bleed and sometimes produce an intermittently positive sputum, and when such complications occur, there is a good indication for their removal.

(v) *Broncho-stenosis.* Complete obstruction of a stem bronchus is usually associated with damage and destruction of the lung tissue beyond the obstruction. Such damage alone will usually demand a formal resection. Occasionally a partial stenosis without lung damage is encountered, and if symptoms such as wheezing or attacks of bronchitis are present, then excision of the stricture (sleeve resection) should be undertaken.

(*d*) *Uncertainty about the diagnosis.*—The incidence of pulmonary tuberculosis in middle-aged males has shown a definite increase of recent years. This age group unfortunately carries a high lung cancer risk—a risk which is rising with the steady increase in the disease. These factors throw a great responsibility on the chest physician not only to make a positive diagnosis of tuberculosis but to exclude the presence of a cancer. It is imperative to seek bacteriological confirmation by all possible means and until such confirmation is obtained the diagnosis of tuberculosis should be suspect. The problem is particularly acute in those patients, often brought to light by miniature mass radiography, who have solitary rounded lesions. Tomography may provide strong circumstantial evidence in favour of tuberculosis in the presence of calcification or of satellite lesions. The problem is not made any easier by the not infrequent occurrence of cancer and tuberculosis in the same patient. If there is any doubt about the possibility of cancer, a thoracotomy is completely justified.

Case I.—J. D., male, aged 47. Admitted to hospital in July 1956 following a mass miniature radiographic finding of a rounded lesion at the right apex (Fig. 2). Tubercle bacilli were found in a smear from the sputum on one occasion and these were subsequently cultured. Tomography showed an irregular solid focus without cavitation, calcification or obvious satellite lesions (Fig. 3). He was given PAS and isoniazid for three months but both the straight X-ray and tomographs showed that the lesion was larger. Accordingly thoracotomy was performed and lobectomy carried out. The specimen (Fig. 4) showed a carcinoma (squamous cell). There was no evidence of a tuberculous lesion in the operation specimen.

(*e*) Surgery may be indicated at a relatively early stage in order to reduce the total length of treatment and enable the patient to get back to work with a reasonable degree of certainty at a specific date. It is usually possible to decide fairly accurately how long it will be after an operation before the patient can return to work. Such forecasting is less certain with medical treatment alone and there is always the possibility of having to employ surgical measures at some later date, although here again long-term chemotherapy is altering the picture appreciably.

(*f*) Patients who have to live abroad under unfavourable conditions can often be rendered more stable and better able to carry on if they have had the advantages of surgical treatment.

II. Pre-operative Investigations

It is unnecessary to underline the importance of an adequate period of observation and treatment with bed rest and chemotherapy before surgical treatment is contemplated. There is good evidence to indicate that the success of surgery is enhanced and freedom from complications is increased if a negative sputum is obtained before an operation is carried out. Should such negativity be unobtainable, the advantages of bacterial sensitivity to drugs, and the disadvantage of bacterial resistance with regard to post-operative complications are also well known.

In the planning of an operation, it is becoming more and more important to determine the precise extent and nature of the pathological lesions present. A complete survey of all earlier films, and the use of both lateral and antero-posterior tomographs is well known. From the surgical point of view, lateral tomographs are often of more value than antero-posterior tomographs because they enable an anatomical localization of lesions to be made more accurately.

The value of bronchography and the potential importance of pulmonary-function studies when planning surgery.—For the past year or more, I have had bronchograms performed on the majority of patients undergoing surgical treatment and on many occasions have demonstrated the presence of unsuspected bronchial lesions which have materially influenced surgical management. The presence of extensive bronchiectasis in an upper lobe which has residual nodulation or cavities, would strongly support a decision to resect the lobe rather than collapse it. Alternatively, the presence of widespread scattered, and perhaps even mild bronchial dilatation in patients with a localized lesion, would make one favour collapse therapy rather than surgery unless the whole of the involved bronchi could be removed.

Case II.—A. F., female, aged 30. This patient had a three-year history of pulmonary tuberculosis with bilateral apical disease. In June 1956 she was submitted for surgical treatment because of a recent relapse with a positive sputum. An X-ray (Fig. 5) showed infiltration in the left upper

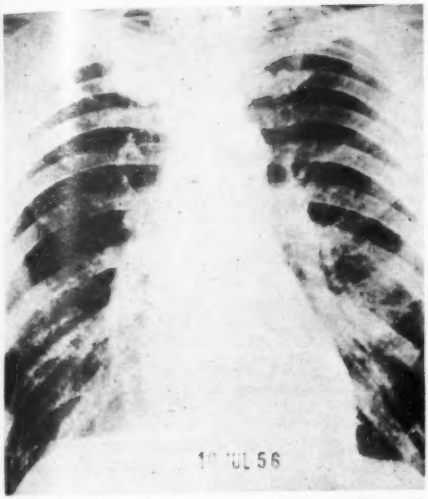

FIG. 2 (*Case I*).—Postero-anterior radiograph (July 1956) showing rounded shadow at the right apex.

FIG. 4 (*Case I*).—Specimen of right upper lobe showing typical peripheral type carcinoma.

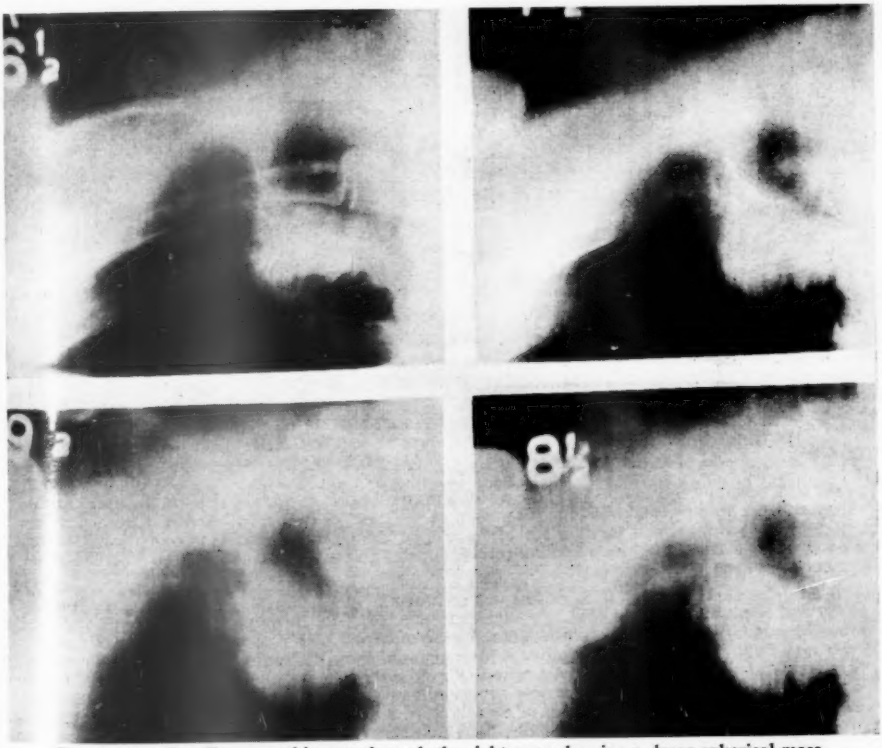

FIG. 3 (*Case I*).—Tomographic cuts through the right apex showing a dense spherical mass without calcification or satellite lesions.

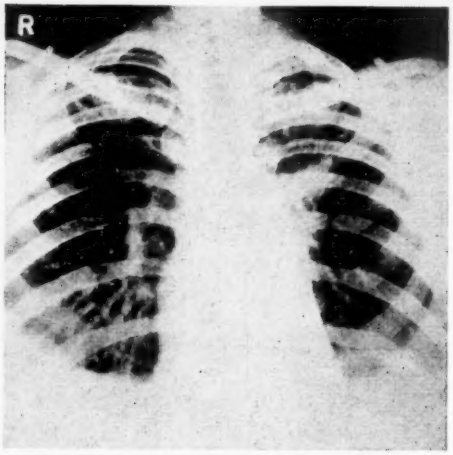

FIG. 5 (*Case II*).—Postero-anterior radiograph showing bilateral apical infiltration.

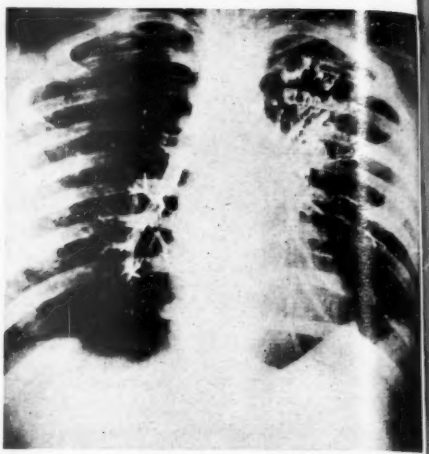

FIG. 6 (*Case II*).—Antero-posterior bronchogram showing gross dilatation of the upper lobe bronchi.

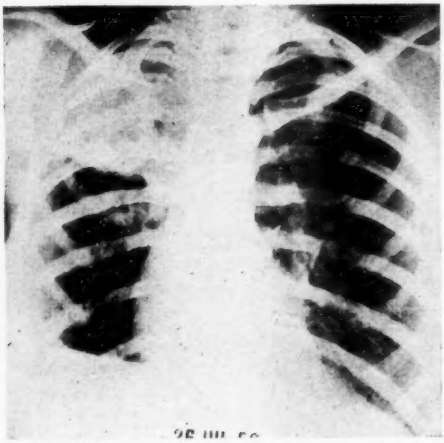

FIG. 7 (*Case III*).—Postero-anterior radiograph (July 1956) showing consolidation of the right upper lobe. The lower lobe appears normal.

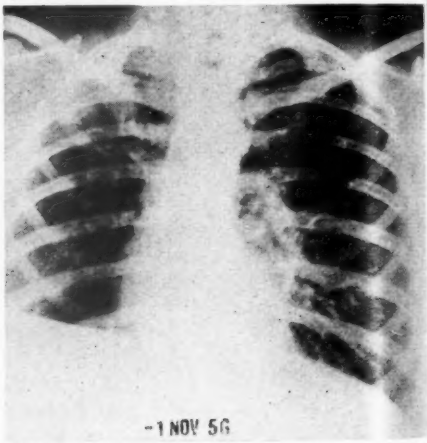

FIG. 8 (*Case III*).—Postero-anterior radiograph (November 1956) after four months' chemotherapy showing considerable clearing of the upper lobe consolidation. Residual nodular disease remains. There is no obvious cavity.

zone with several small cavities. There was infiltration but no cavitation at the right apex. At this stage collapse therapy was contemplated in view of the presence of bilateral disease. Bronchograms (Fig. 6), however, showed that the whole upper lobe was shrunken and bronchiectatic. Collapse therapy might have given disappointing results in such a case and accordingly an uneventful left upper lobectomy was carried out.

Case III.—G. I., female. This patient was admitted in July 1956 with a consolidated right upper lobe and a positive sputum (Fig. 7). She responded well to chemotherapy and an X-ray four months later (Fig. 8) showed considerable improvement but still a good deal of residual nodular disease though the sputum was negative and tomographs showed no cavitation. Resection was contemplated at this stage but a bronchogram (Fig. 9) showed not only gross bronchiectasis in the damaged right upper lobe but extensive bronchiectasis in the middle and lower lobes. Resection would have necessitated the removal of the whole lung which was not considered to be warranted as a prophylactic measure. Accordingly, long-term chemotherapy was instituted and the question of surgical treatment was deferred.

In a number of instances, completely unsuspected bronchiectasis has been demonstrated in the apical lower segment in patients with upper lobe disease where a resection was contemplated. I believe that leaving such a segment in the body, possibly with a raw upper surface, is responsible for some of the post-operative complications. In such cases, the apical lower segment should be removed in addition to the upper lobe, or resection should not be carried out at all.

Bronchography has been entirely safe and there has been no suggestion of spread of disease following its use. It is an investigation which has important bearings on the nature of surgical treatment which is to be carried out.

Pulmonary function studies are, at present, of limited value. The over-all function can be quite accurately determined by simple clinical tests and interrogation.

Bronchospirometry gives valuable information about the difference in function of the two sides, but the method is somewhat limited. The development of methods for determining the function of individual lobes should be of tremendous assistance in the difficult problem cases. Such detailed lung function studies will be of immense value when they can be applied to clinical problems.

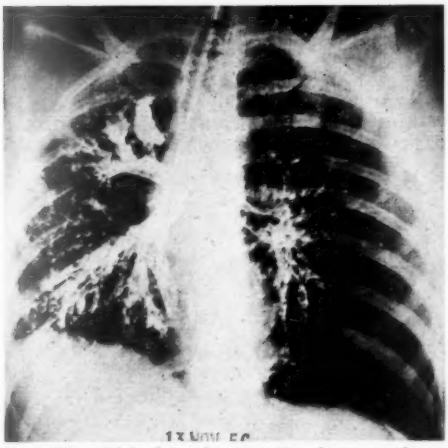

FIG. 9 (*Case III*).—Right bronchogram showing gross bronchiectasis of the right upper lobe.

III. Methods of Surgical Treatment

Most people will agree that the ideal treatment is resection but in varying proportions of cases the ideal treatment cannot be carried out, and alternative methods must be employed because they are safer. Resection has the advantage that it removes the bulk of the disease and it does not interfere with the function of the adjacent normal lung. A surgeon has to aim at removing all the obvious or gross disease, and it is for this reason that fairly complete investigations with tomography and bronchography are required before operation. The risks of complications if much disease is left behind are appreciable and, under these circumstances, many surgeons prefer to carry out some form of collapse therapy. The complications of resection are, on the whole, more serious than those of collapse therapy, and although not common, they carry a much higher mortality and morbidity rate.

The complications concerned are bronchopleural fistulæ, empyema and spread of tuberculous disease. These complications are higher amongst the sputum-positive cases and amongst those who have developed bacterial resistance. These complications must always be borne in mind when considering possible surgical therapy.

The contra-indications to resection are:

(1) Active or extensive disease on the same or opposite side which would not be included in the resection.
(2) Poor respiratory reserve.
(3) The presence of chronic bronchitis, emphysema or asthma.
(4) In the elderly.
(5) In those with active endobronchitis.

The alternatives to resection can be considered under the heading of thoracoplasty or one of the modifications, such as Holst thoracoplasty, Björk thoracoplasty or plombage. The very fact that thoracoplasty, or its modifications, is employed as an alternative to a resection where the latter is contra-indicated, means that it is never really legitimate to compare the results of the two forms of treatment except where such cases can be regarded as truly comparable.

Dr. Peter Stradling: *The Chest Clinic Management of Pulmonary Tuberculosis*

The modern chest clinic has wide duties relating to the diagnosis and management of many chest conditions but the following brief remarks are restricted to its activities in relation to pulmonary tuberculosis.

The majority of tuberculous patients and their families can be managed solely from a chest clinic without reference to sanatorium, but an efficient chest clinic must provide, as an integrated whole, preventive, diagnostic and treatment services.

DIAGNOSIS

The prognosis for an individual tuberculous patient varies with the extent of the lesion when first discovered; Springett (1956) has recently confirmed this even for minimal lesions. Still not fully realized, however, is the possibility of rapid spread, particularly in young adults (Fig. 1A, B).

A

B

FIG. 1A and B.—The radiographs of a young man (R. N.) who declined treatment. A, on diagnosis; B, four months later.

Diagnosis at the earliest possible opportunity is thus a vital and self-evident clinical necessity. But prompt diagnosis is equally important administratively because the simple treatment methods that are then effective lead to a minimum of social disturbance. The first duty of a chest clinic, as stressed by Toussaint and Pritchard (1944), must thus be to provide diagnostic aid to General Practitioners from whom are referred, either directly or via hospitals, by far the largest proportion of new cases of pulmonary tuberculosis.

To assist early diagnosis a most important addition to ordinary consulting clinics is a freely available chest radiography service for practitioners. Such group radiography is a very sound diagnostic method because it is unusual for disease to pass the early stages

without the patient experiencing recognizable symptoms. I find about 25% of the films are abnormal and a great variety of conditions are revealed (Table I).

If such a routine radiography service is to be of high standard certain precautions must be taken. In the first place the human error inherent in the reading of all radiographs must be reduced as far as possible so that lesions shall not be missed. This can be attained in part by dual independent reading of the radiographs. In addition there is a proportion of tuberculous lesions the shadows of which are difficult to see because they become involved in those cast by the bony thorax. These can usually be revealed by a lordotic view which also prevents many unnecessary recalls. It is thus a good routine to take two views and to practise their independent dual reading (Stradling and Johnston, 1955). 10% to 30% of lesions will be missed if this is not done.

A routine radiography service should form a vital part of the National Health Service and be provided in every chest clinic. Prompt diagnosis means easier prevention and simpler treatment.

TABLE I.—A BRIEF ANALYSIS OF THE FINDINGS IN THE X-RAY SESSIONS HELD AT HAMMERSMITH CHEST CLINIC DURING 1955

X-ray Sessions: 1955

Total No. of patients X-rayed		3,034
Found normal	.. ..	2,263
Found abnormal	.. ..	771
Abnormalities		
Pulmonary tuberculosis	.. 26	(0·9%)
Carcinoma of bronchus	.. 15	(0·5%)
Pneumonia	 125	(4·1%)
Cardiovascular abnormalities	 142	(4·7%)
Miscellaneous abnormalities	 292	(9·6%)
Diagnosis pending	.. 143	(4·7%)
Lost sight of and transferred	 28	(0·9%)
	771	(25·4%)

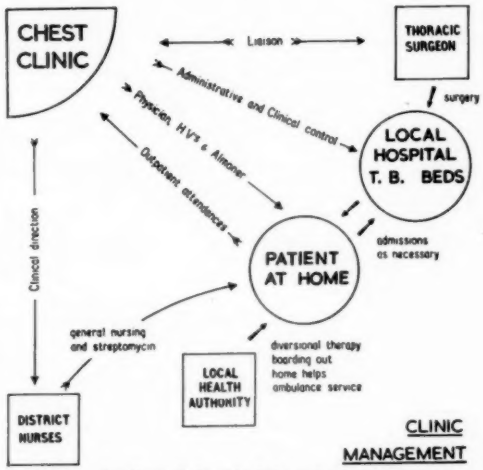

FIG. 2.—Outline of the administrative arrangements for operating a clinic management service.

(Reproduced from Stradling (1955) by kind permission.)

PLACE OF TREATMENT

The aim of treatment in a case of tuberculosis is not only the repair of pulmonary damage but rapid return of the patient and his family to social independence: this implies action on a much wider front than pure therapeutics and it is obvious that we must choose that method of treatment which is not only successful but involves the least possible disturbance to family and working life. Logically this implies that part or all of the treatment should be on a domiciliary basis: but it is not necessary to demand too high a standard of the home. Soon after the last war long waiting lists for sanatoria often enforced treatment outside these institutions. The results of such action, even before chemotherapy, equalled those of sanatoria (Stradling, 1951, 1955). Now chemotherapy has proved so powerful that a combination of local hospital, domiciliary, and out-patient treatment (for which I have coined the phrase "Clinic Management"), is an entirely acceptable alternative to sanatorium. The scheme is outlined in Fig. 2. The extent to which such a service can handle the local problem, even without an adequate number of local hospital beds, is indicated in Fig. 3.

I believe such Clinic Management to be the method of choice: apart from monetary saving, the advantages are great. There is continuity of medical treatment so important to both patient and physician. Long separation from the realities of life, so common in sanatoria, is avoided, thus abolishing the need for prolonged rehabilitation. The patient derives comfort and inspiration from the frequent visitors received when he is in the local hospital, and is not separated from his family at all when managed at home or as an out-patient. In short he is happier than in sanatorium.

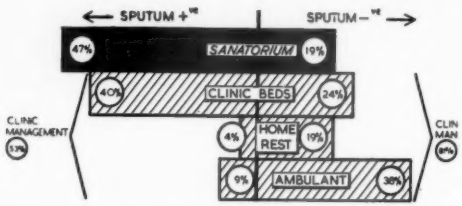

FIG. 3.—Methods of management used for the 114 new notifications in 1955. For those patients entering sanatorium the reason for admission was in every case an unsatisfactory home at a time when the local hospital beds were full.

The problem of returning to work is also diminished. The minimal disruption of social life enables the majority of patients to return quite quickly to their previous employment unless this is strikingly unsuitable. In more difficult cases the clinic Almoner (and Disablement Resettlement Officer where necessary) plays a vital part in assisting early re-employment before the patient becomes work-shy.

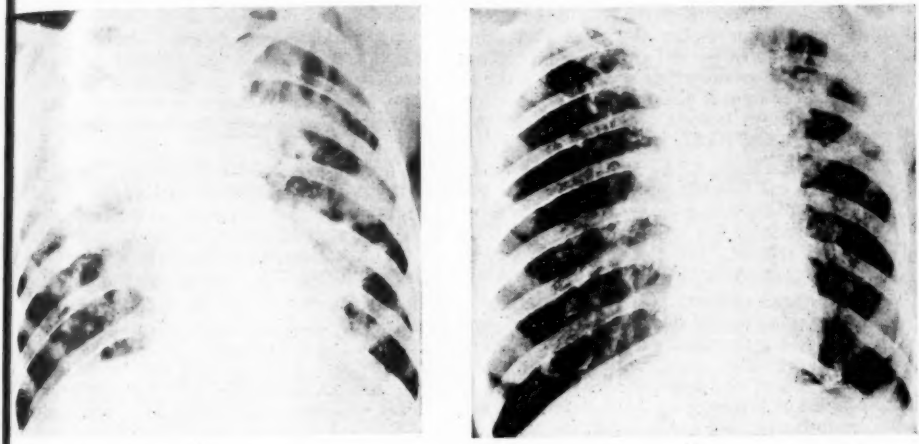
METHODS OF TREATMENT

Small lesions of rather doubtful or low activity form a special and increasingly important group. 40% of my new cases now have disease involving less than one radiological zone, and during the last five years the proportion of patients presenting with a positive sputum has steadily fallen (72% in 1951; 38% in 1955).

With such patients, who often feel well, it is of the utmost importance to avoid unnecessary disruption of their normal family life: it is so easy to produce neurosis which is far more troublesome than minimal tuberculosis. One should remember also that there is always a good chance of the patient recovering if his disease were never discovered. The many calcified lesions seen in routine X-ray surveys bear witness to this fact. On the other hand, particularly in the younger age groups and as already shown in Fig. 1, such lesions can advance in an unpredictable and rapid fashion.

Here then is a group ideally suited to ambulant chemotherapy. It is my practice with these individuals, after taking laryngeal swabs, to start such treatment as a therapeutic trial: often without interrupting their work. If, after some weeks, the lesion is smaller, then it was obviously active and treatment was indicated. But since it has improved, treatment is effective on an ambulant basis and there is no need to change it.

Overtly active disease in a sick patient presents a greater problem and needs a much more comprehensive service than the simple dispensing of drugs to an out-patient. Nevertheless, on a background of chemotherapy, this can be completely and successfully provided under Clinic Management.



All patients, when enough "clinic" beds are provided, can be treated either in hospital, at home or ambulant, according to social circumstances and disease activity. It is the latter which is often difficult to assess and a valuable biochemical aid, considerably more accurate than the E.S.R., has recently been demonstrated in the albumin/a_2-globulin ratio obtained from serum electrophoresis (Gilliland *et al.*, 1956). This ratio falls progressively as disease becomes more active and correlates well with careful clinical assessment.

A fundamental issue in the medical management of tuberculous patients is whether bed rest is any longer essential. The final answer must await a properly organized, statistically valid trial involving larger numbers of patients than can be provided by one clinic area. Nevertheless, my clinical impression is that bed rest is no longer essential for the tuberculous provided they do not feel ill. Some of my patients, treated on an ambulant basis, even with obviously active or cavitating disease, have done so well that I wonder whether those remaining in bed are doing so unnecessarily.

The management of tuberculous patients can thus be undertaken outside sanatoria with chemotherapy replacing bed rest as the basic treatment. But here I would stress the importance of *multiple* drug treatment. It is my practice to give all three anti-tuberculous drugs in full daily doses until the bacterial sensitivities to them are known; 5% of newly diagnosed and previously untreated patients now excrete bacilli resistant to one or more of the three anti-tuberculosis drugs (Fox *et al.*, 1957). If thus found suitable, daily streptomycin + isoniazid alone are then usually continued for three to six months before PAS + isoniazid are substituted as a more convenient combination for the trustworthy ambulant patient. Many patients, however, continue daily streptomycin + isoniazid for

very much longer, Intermittent drug therapy (particularly one intermittent with the other continuous) is *not* employed in view of the risk of resistant bacterial strains emerging.

In many units chemotherapy has practically replaced artificial pneumothorax and pneumoperitoneum. Even advanced cases, usually quite unsuitable for surgery, do remarkably well on prolonged drug treatment alone or in combination with cortico-steroids (Fig. 4A, B).

A B

FIG. 4A, B.—The radiographs of a young woman (R. M.). A, on diagnosis; B, three years later. Desperately ill on diagnosis with tuberculous meningitis in addition to the extensive pulmonary disease, she received daily streptomycin, para-aminosalicylic acid and isoniazid for eighteen months. Although breathless she has been sputum-negative since completing her first three months of treatment and is again managing her home and family.

When suitable facilities are available surgical cases can also be managed well outside sanatorium. Major operations were performed by Mr. Cleland or members of his team on 58 tuberculous patients in my small 27-bedded unit over a recent five-year period. These included 23 resections, 15 thoracoplasties, 25 plombage operations and a small miscellaneous group. No serious complications occurred and only one patient was not quiescent a year after operation.

All surgical treatment is undertaken on a background of continuous chemotherapy which is maintained long after a patient returns to work. But a decision on surgery (now most often resection) is usually reached within three to six months of diagnosis so that work is resumed as soon as possible. Chemotherapy is so successful, however, that I sometimes wonder whether surgery is offered too frequently.

DIFFICULTIES

Two points need special consideration. In the first place there is the danger of infection to contacts if the sputum-positive patient is managed at home. But the preventive work of a chest clinic can be very effective. In the worst cases the danger is overcome by admitting the patient to the local hospital tuberculosis ward from diagnosis until sputum conversion is obtained. During this isolation period BCG is given to the tuberculin-negative contacts. Health Visitors are invaluable in persuading contacts to attend the clinic and in teaching how to avoid infection. Although modern chemotherapy rapidly renders a patient negative, the proper disposal of sputum from the infectious home-bound patient is still of importance and the Miltherex method is probably the best available at present (Stradling, 1953).

In this way the infectivity of tuberculosis can be very greatly reduced. Support to such a claim is given by the observed drop in the number of cases of active tuberculosis found by contact radiography at Hammersmith during the last few years: 7·5 per thousand films taken in 1951 falling to 1·0 per thousand for 1955. Furthermore during 1952 over half of the 23 contacts notified had developed their disease *subsequent* to the notification of the index case while in 1955 all of the 6 contacts notified were discovered at their *first*

attendance immediately after the diagnosis of the source case. The great improvement in the contact *follow-up* picture is probably due partly to the protection afforded by the BCG given to all tuberculin-negative contacts since 1950, and partly to the reduction of infectivity following the wider use of chemotherapy. The lesser drop in the number of contacts notified on *first* examination is probably a reflection of the earlier diagnosis being obtained. These findings stress the continued vital importance of the first contact examination but justify a more selective attitude to continued contact follow-up.

The most serious criticism that can be levelled at the management of the tuberculous as out-patients is the fact that chemotherapy is not closely supervised. There is the possibility of a patient either taking too small a quantity of a drug (particularly PAS) or of omitting it altogether, thus risking the emergence of resistant strains of tubercle bacilli. Such a criticism is not unique to out-patient therapy, however; to a lesser extent it can also be levelled at hospitals, where it is not always possible to supervise the consumption of every dose of PAS.

But even under Clinic Management much can be done to circumvent the danger. Health Visitors are constantly encouraging the patients to report any difficulties with the drugs instead of deceiving the doctor. Much time is spent on careful explanation to the patients; explanation of the importance of dual drug therapy regimes in obtaining results and preventing relapse. Where there is doubt about the trustworthiness of an individual, isoniazid can be given at the time of a streptomycin injection when the nurse can see that it is swallowed.

To those patients at work the factory medical organizations can be very helpful by undertaking to give daily streptomycin injections or supervising the consumption of cachets. District nurses will often give injections in the evening and it is possible to teach selected patients to give their own streptomycin. Ambulant oral chemotherapy can be offered as cachets or powders containing both PAS and isoniazid in appropriate doses; interruption of treatment then stops both drugs and so minimizes the danger of resistance. Urine tests are also available which reveal the presence of PAS. Some surprising results are obtained with routine urine testing (Simpson, 1956) but to retain the test's validity it is most important that the patients should not know its significance, which can be completely vitiated by a single dose of PAS taken before attending the clinic.

Infantile Cortical Hyperostosis; A Review of the Clinical and Radiographic Features[1]

By John Caffey, M.D.

New York City

Infantile cortical hyperostosis, hereafter called ICH, was first named and recognized as a separate entity in 1945 [1]; however, several observers, beginning with Röske in 1930 [2] had reported individual cases, similar to ICH, which they could not classify. The single Italian infant described by de Toni in 1943 is of special importance because he early recognized the congenital and regressive aspects of ICH. This disease is probably a new entity because, prior to 1930, there are no recorded descriptions, either clinical or radiographic, of a syndrome similar to ICH; it is unlikely that earlier clinicians would have overlooked its

Fig. 1.—Prenatal infantile cortical hyperostosis in a fœtus 31 weeks of age. A, massive hyperostoses in the bones of the extremities in a lateral projection of the fœtus *in utero*. B, photograph of the dead fœtus after delivery by Cæsarean section. Swellings of the face and extremities are similar to those of postnatal ICH. C, rœntgenogram of the fœtus *ex utero* shows hyperostoses in the mandible, ribs, and tubular bones in the extremities which are similar to those found in postnatal ICH [C, Reproduced by kind permission; Bennett and Nelson, 1953].

[1]From the Departments of Pediatrics and Radiology, College of Physicians and Surgeons, Columbia University, and the Babies Hospital, New York.

striking and distinctive clinical and radiographic manifestations. With the passing of only a few years, it has become clear that the disease is not a rare one. Several cases are encountered every year in almost all of the larger pædiatric clinics in the United States and Canada, and almost every pædiatrician has seen one or more cases. One pædiatrician in North Carolina has recognized 11 cases in his own practice. Groups of cases have now been reported from all parts of the world from a wide variety of social, racial, and cultural environments.

The clinical and radiographic features have now been described in more than one hundred cases and it is likely that our knowledge of these aspects is almost complete. One of the most striking clinical features is the early age of the patient at onset of the disease. There are no valid cases in which the age at onset has been greater than 5 months; in our cases the mean age at onset is 9 weeks. In several cases ICH has been well developed at birth, both clinically and radiographically. Thick lesions in the long bones have been demonstrated *in utero* radiographically during the last month of gestation in two fœtuses which exhibited the classical disease postnatally [3]. Bennett and Nelson [4] found radiographic and anatomical

A B C D

FIG. 2.—Characteristic facial swellings of ICH infants 3 to 4 months of age; A, B, C, D.

changes, which simulated postnatal ICH, in a dead fœtus at the 31st week of gestation (Fig. 1). Similar findings were reported by Jenkinson [5] in a dead fœtus at the 24th week of gestation. The prenatal disease and limitation of onset of the postnatal to the first few months of life, both point to the importance of transmission from the mother as an important factor in pathogenesis of all cases.

The postnatal disease commonly begins suddenly with swelling of the jaw and face (Fig. 2) without premonitory signs. The infant usually becomes feverish and hyper-irritable at the same time. Conjunctivitis has preceded the facial swelling in several cases. In a few cases swellings have first appeared in the leg or arm, and the face became swollen three to four days later. In the thorax swellings may be present over the scapulæ, clavicles, or ribs on one or both sides (Fig. 3). In one case the parietal bone was swollen. Swellings in the extremities are accompanied by regional limitation of movement and tenderness but never by discoloration or œdema of the overlying skin, or local increase in heat. The regional lymph nodes have not been enlarged in our patients. The swellings are wooden-hard and

FIG. 3.—Characteristic facial swellings with multiple swellings in the right arm and hand, the left forearm and hand, the right thoracic wall and all of the right leg. This infant was 18 weeks of age; the disease began with right-sided facial swelling at 7 weeks of age. The intense swellings of the soft tissues have ballooned out the parts and split the superficial layers of skin in the left forearm leading to coarse desquamation. All of the bones beneath these swellings showed massive hyperostoses. There was no hyperostosis in the left humerus over which the skin is loose, with no swelling.

are deeply situated and fixed to the underlying bones; exact edges of the swellings are difficult to establish accurately, especially in the neck, where the swellings fuse with the thick fat infantile neck. Fever may be absent, or moderate and of short duration, or high and prolonged. Lack of fever is common when the disease is limited to the mandible. Mild or moderate pallor and anæmia are present at onset or develop early in the disease in more than one-half of the cases. The only laboratory finding of positive value is increase in the sedimentation rate of the red blood cells; roughly, this varies directly with the activity of the lesions. A moderate polymorphonuclear leucocytosis is the rule during the febrile phases. All bacterial, viral and immunological studies of the blood and biopsy specimens have given negative results. The urine and cerebrospinal fluid have been normal in all cases in which they were examined. Chemical and vitamin tests on the blood have also proved negative.

The clinical course of the disease is highly variable. In the mildest cases, facial swelling disappears completely after a few weeks. In moderate cases, with multiple swellings and tenderness, the clinical disease may last for several weeks or months with sudden appearance

FIG. 4.—Massive external cortical thickening of the mandible. The coronoid process is swollen and thickened but the neighbouring condylar process is not affected. Much of the cortical thickening is in the caudal direction (arrow). The infant was 3 months of age; facial swelling was detected clinically four weeks before this film was made. The mandible is filmed in oblique right lateral projection.

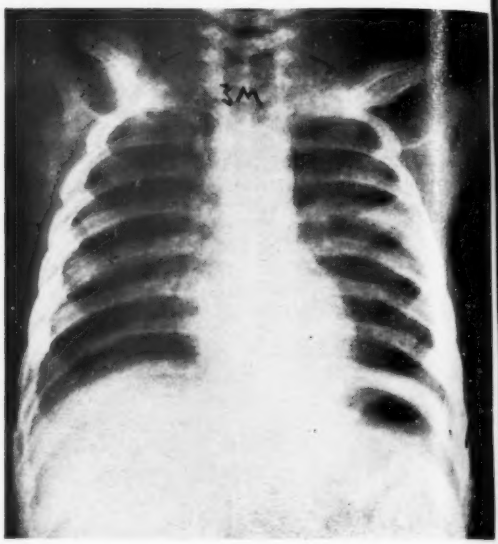

FIG. 5.—Multiple cortical hyperostoses in the clavicles and several ribs in both sides of the thorax in an infant 3 months of age whose face first became swollen during the ninth week of life.

of new swellings in one site while they are subsiding in other places. A single lesion may begin to regress and suddenly a new swelling will flare up in exactly the same site. The disease may be limited to two or three swellings for several weeks and then new swellings will appear suddenly in several other sites with rise in fever and sedimentation rate. These natural fluctuations make difficult the estimate of the efficacy of therapeutic agents. The swellings appear to regress by simple shrinkage; they never soften, penetrate the skin or discharge exudate of any kind. In some severe cases swellings have persisted for eighteen to twenty months without regression, and in others facial swellings and fever have recurred periodically for as long as seven years after complete subsidence of the original infantile attack. At least 3 patients have died.

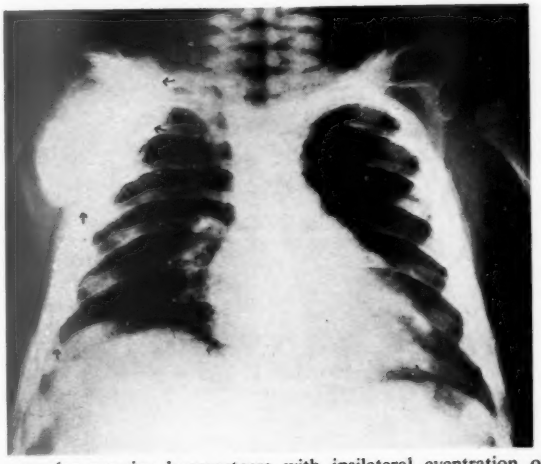
The radiographic findings are identical wherever they are found. The cortical walls of the bones which underlie the swellings thicken externally (Figs. 4, 5, 6). These cortical thickenings are often found in bones where swellings have not been identified by palpation. In all of our patients in whom the mandible has been examined radiographically, both early and late, this bone has been thickened. The clavicles have been involved in about one-half of the patients; the tubular bones, including ribs, in about one-third; the scapulæ in about one-quarter; and more rarely, the metatarsals, the ilia, and the parietal bones. In 2 cases, scapular hyperostoses have been accompanied by ipsilateral eventration of the diaphragm (Fig. 7). In the chronic hyperostoses, the bones finally heal by reaming out of the hyperostoses which produces a thin-walled bone with dilated medullary cavity (Fig. 8). Acute and chronic hyperostoses in the rib are shown in Fig. 9. Patchy sclerosis of the mandible was evident in the mandible, six and three-quarter years after the onset, in one chronically recurring case (Fig. 10).

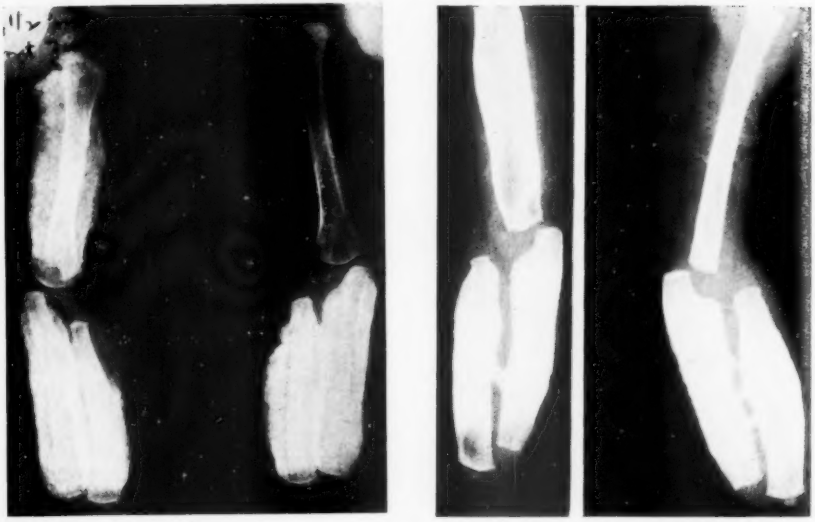
Morbid anatomy has been studied incompletely in biopsy specimens; necropsies have not been reported in the classical form of the disease; and there is a dearth of biopsies in the earliest phase of the swellings. All pathologists agree that the hyperostoses are made up of normal but immature lamellar bone. In many cases there has been no microscopic evidence of inflammation; in other cases the presence of cellular infiltrates has suggested inflammatory reaction. There is no anatomical evidence that subperiosteal hæmorrhage is a factor in the cortical thickenings. In the acute disease the periosteum is loose and thickened and often has a gelatinous character with many mitotic figures in the cells. This feature has led to the erroneous diagnosis of sarcoma in several cases, especially in specimens taken from the

A

B

FIG. 6.—Radiographs of the cortical hyperostoses in: A, the humerus and ulna of an infant 11 weeks of age whose face first became swollen at 2 weeks of age; B, in the femora and tibiæ of an infant 14 weeks of age whose face first became swollen during the seventh week of life. The absence of changes in the metaphyses and epiphyseal ossification centres readily differentiates this disease from scurvy.





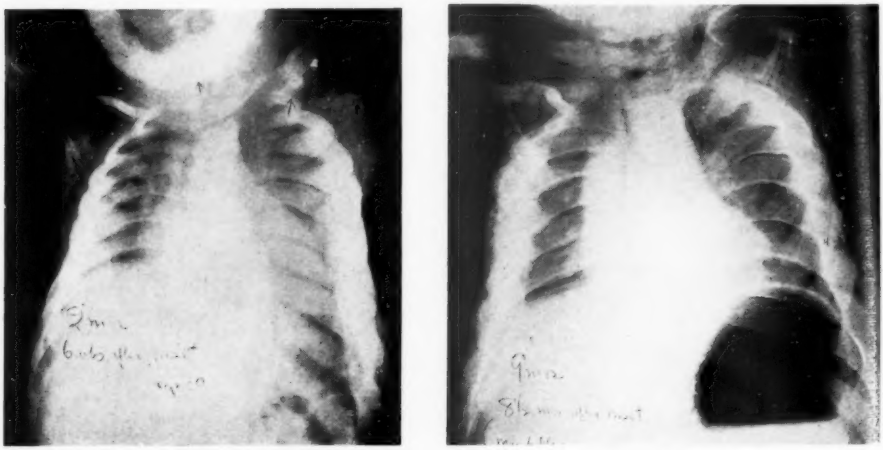


FIG. 7.—Right scapular massive hyperostoses with ipsilateral eventration of the diaphragm (arrows) of an infant 9 weeks of age who had been ill three weeks when this film was made. We have seen one other infant with ipsilateral hyperostoses of the scapula and eventration of the diaphragm. Both clavicles and several ribs on both sides are also thickened.

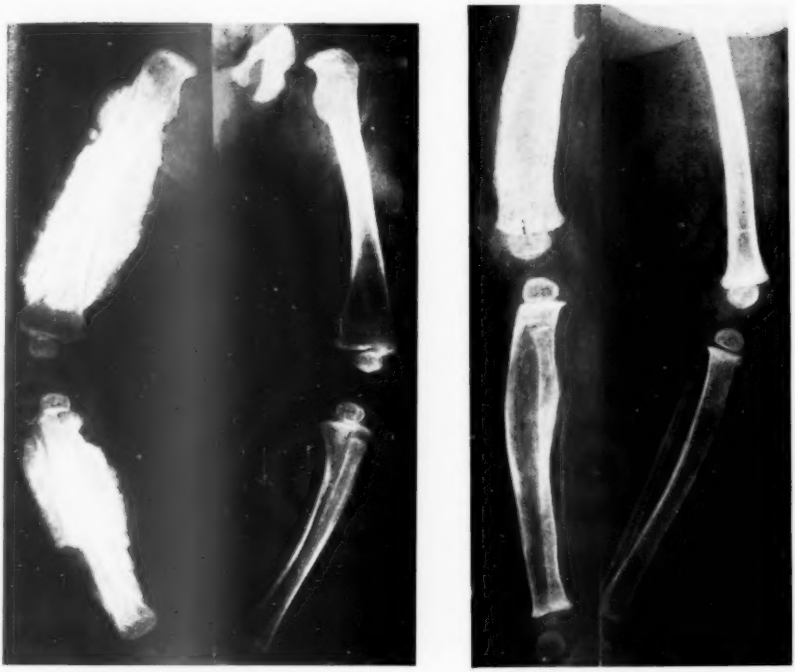

A B

FIG. 8.—Acute and chronic ICH with persistence of bone lesions for more than 29 months. The disease began at 7 weeks of age with facial swellings and rapidly extended to the thorax and extremities (*see* Fig. 3). A, arms at 4½ months show massive cortical thickening of the right humerus, both radii and both ulnæ. In the forearms, impaction of the thickened bones has dislocated the radius out of the elbow on both sides. B, in the arms at 12 months, the bones are still greatly enlarged in girth; bridges of bone anchor each radius to its ulna. Each radius is dislocated out of its elbow. The right humerus is still greatly enlarged but its hyperostosis has been partially reamed with corresponding increase in its medullary cavity. (*Continued on page 15.*)

A B

FIG. 9.—Acute and chronic hyperostoses in the ribs. A, at 2 months, six weeks after first facial swelling. All of the ribs on the left are massively thickened and sclerosed; the intercostal spaces are correspondingly narrowed. In the right ribs there are similar but less marked thickenings. The first and second right ribs are normal. The left clavicle and scapula are thickened and sclerosed. B, at 9 months the ribs on both sides are still massively swollen and the intercostal spaces are narrowed. These bulky ribs in contrast have thin cortical walls and greatly dilated marrow cavities in contrast to A. At 18 months, the findings were slightly less marked than in B.

C D

FIG. 8.—In C, legs at 4½ months, there are massive rough hyperostoses in the right femur and right tibia. In the left leg where there were no soft tissue swellings (*see* Fig. 3), there are no hyperostoses. In D, legs at 15 months, the hyperostoses in the right femur, tibia and fibula have largely disappeared owing to erosion of the thickened cortical walls from within, which has resulted in bulky bones but with thin cortical walls and correspondingly large medullary cavities. At 32 months, these thin-walled bones had been restored to almost normal shape; the medullary cavities had shrunk toward normal, and the cortical walls had re-thickened to approximately two-thirds of their normal thickness.

thickened scapula. The mucinous thickening in the periosteum usually extends directly into the neighbouring tendons, fascias, and intermuscular septa. In specimens taken several weeks after the onset, extensive muscular necrosis with fibrous replacement has been demonstrated. Sherman and Hellyer [6] found obliterating intimal proliferations in the regional small arteries; some think the arterial lesions are primary.

Although much has been learned about the clinical and radiographic manifestations of ICH, causation and pathogenesis have become even greater puzzles with the study of more cases. Numerous causal agents and mechanisms have been suggested but all have been found wanting—bacterial infection, viral infection, allergy, trauma, hormonal disturbance, collagen disease, and genetic transmission. The identification of the well-advanced disease *in utero* and at birth, and the limitation of the age of onset after birth to the first five postnatal months all suggest that the mother is the source of the disease. It is my belief that study of the mothers will finally unravel this baffling problem of the cause and pathogenesis in the infant.

Treatment was generally symptomatic until it became evident that the disease is occasionally fatal and not infrequently recurrent and chronic, sometimes with crippling residual changes. The adrenocorticosteroids are highly effective in all phases of the disease and we believe all patients should be treated in view of the uncertain prognosis in all cases, owing to the rapid and unpredictable fluctuations in the disease. Cortisone should be given in doses of about 200 mg. daily during a period of two to three weeks. Recurrence is likely when the cortisone is stopped at the end of one or two weeks. Dosage should be reduced gradually to prevent rebound phenomena which have been severe after sudden stoppage of the

A

B

FIG. 10.—Chronic recurrent ICH of the mandible from the third month to the seventh year. At 3 months the patient had the classical severe scattered disease. After several weeks the disease subsided but later, at intervals of three to six months, swellings of the jaw recurred. In these lateral oblique projections of the mandible, the right side of the bone (A) shows a severe patchy sclerosis and the left side (B) is normal radiographically.

steroid. With proper treatment desperately ill patients become asymptomatic after a few days. External swellings gradually subside and the radiographic changes may be visible in the bones for several months after complete clinical cure.

Section of Urology

President—CUTHBERT E. DUKES, O.B.E., M.D., M.Sc., F.R.C.S.

[*October* 25, 1956]

"Behind the Scenes in Urology"

PRESIDENT'S ADDRESS

By CUTHBERT E. DUKES, O.B.E., M.D., M.Sc., F.R.C.S.

I AM privileged to be the first pathologist to be elected President of the Section of Urology. This Section of the Royal Society of Medicine is thirty-six years old. Sir Peter Freyer was its first President, Lord Horder the second, Sir John Thomson-Walker the third, and Sir Walter Langdon-Brown the fourth. Since then for a period of thirty-two years without interruption the presidential chair has been occupied by a surgeon.

My main theme will be the past history of this Section and my personal recollections of some of its early Presidents. In preparation for this let me first recall some details with regard to the formation of this Section thirty-six years ago.

The Inaugural Meeting of the Section of Urology was held in this building on March 17, 1920. The President of the Royal Society of Medicine that year was Sir Humphry Rolleston. He took the chair, and eighteen Fellows and members were present, but, unfortunately, the list of names of those present has not been preserved.

The first item on the Agenda was the choice of Officers, and the following were elected:

President ..	Sir Peter Freyer
Vice-Presidents	Sir Cuthbert Wallace
	Sir Thomas Horder
Hon. Secretaries	J. W. Thomson-Walker
	Cyril A. R. Nitch

I once asked a very senior member of this Section which of the Founder Members had been the most active "behind the scenes" in promoting the formation of this Section, and he replied without a moment's hesitation "Sir John Thomson-Walker". Evidence for this is provided by the fact that at the Inaugural Meeting of the new Section he was elected the first Honorary Secretary. The President of a new Society is often only a figure-head. If you want to discover the real prime mover you must notice who gets elected as its first Secretary!

Only one of the original officers of this Section is still alive, Mr. Cyril Nitch, now living in retirement at Yeovil in Somerset. There are only three surviving "original members", distinguished in our official list by the letters "O.M.", namely, Lord Webb-Johnson, Mr. J. B. Macalpine, and Mr. Ogier Ward.

Apart from these original members, the most senior ordinary members of the Section at the present time are Sir Zachary Cope, Mr. Clifford Morson and Mr. Kenneth Walker, all of whom were admitted in 1920.

If a prize were awarded to the member of this Section who had held office longest it would, without a doubt, go to Mr. Clifford Morson, whose record is as follows: Joined the Section in 1920, elected Representative on Library Committee 1924, Secretary 1925–1927, Vice-President 1927–1931, Representative on Editorial Committee 1932, President 1933, Representative on Editorial Committee once more in 1935, an office which he has held continuously ever since. He has been a member of the Council for thirty of the thirty-six years of the Section's existence.

FIRST PRESIDENTS OF SECTION

Anyone elected to the office of President in a Society such as this during its early formative years is bound to leave his mark on the organization over which he presides, and the first four Presidents of this Section certainly did so. It is my impression now that each of these was what Emerson would have called a "representative man", and that each, perhaps unconsciously, made a unique contribution to the life of this Section. All four were men of exceptional ability and held in the highest esteem by their colleagues. Though they varied greatly in character and attainments, they were united by a common interest in urology.

SIR PETER FREYER

The first President of this Section was Sir Peter Freyer, who was then 69 years of age and at the height of his fame and professional reputation. It was twenty-four years since, on his return from India, he had been appointed to the staff of St. Peter's Hospital, and just twenty years since he had carried out the first successful suprapubic prostatectomy operation one dark December day in 1900.

I am able to show you photographs of pathological specimens derived from Freyer's first prostatectomy case, and also photographs of the patient's notes but since this is the first time this information has been made public, I must first relate how it was obtained.

I must begin by explaining that soon after my appointment as pathologist to St. Peter's Hospital in 1930, I was given custody of the Freyer Collection of Prostates, which for some years had been stored in a cupboard below a book-case in the Board Room. In this cupboard there were also a few other precious trophies and a drawer containing some 20 or 30 urinary calculi reserved for postgraduate lectures.

I consulted with Mr. Swift Joly, and when we began to sort out the Freyer Collection of Prostates we found a big jar containing a post-mortem specimen of a bladder, prostate and urethra, to which was attached a label marked with the initials "J. T." "Ah", said Mr. Joly with obvious delight, "John Thomas, the first patient on whom Freyer did his prostatectomy operation thirty years ago."

Mr. Joly explained that the patient had survived the operation for more than twelve years, and that Sir Peter Freyer had kept in touch with him regularly during this time by promising the relatives that they should be handsomely rewarded if, after the decease of John Thomas, a post-mortem examination could be performed and the pelvic organs retrieved. Mr. Joly thought that the patient had died in St. Pancras Infirmary just before the First World War.

FIG. 1.—Sir Peter Freyer.

FIG. 2.—Organs from Freyer's first prostatectomy case.

This museum specimen marked "J. T." remained in my charge for the next twenty-six years, but I did nothing to substantiate Mr. Joly's story until a few months ago, when it occurred to me that I might search through the hospital records to discover the name and initials of the patient on whom Freyer had performed his first prostatectomy operation, to see if they corresponded with the information given me by Mr. Joly. I did so, and am much indebted to the Records Clerk of St. Peter's Hospital who eventually found the bound volume of notes of all cases under the care of Sir Peter Freyer. Therein we confirmed the fact that in the month of December 1900 a patient named John Thomas, aged 69, had been admitted for prostatic obstruction and had been treated surgically by Freyer. Here are two extracts from this patient's notes.

EXTRACT FROM PATIENT'S NOTES DATED DECEMBER 1900
OPERATION (P. J. F.) GAS AND ETHER

"Suprapubic incisions: incision into mucous membrane of bladder on to right prostatic lobe: *this shelled out quite easily*. Apparently an adenomatous growth not very hard—more elastic than doughy. Corresponding incision into mucous membrane over left lobe which was treated in the same way. This was smaller but apparently of exactly the same consistency. When the right lobe was removed and got out of the way a small median lobe was felt about the size of a marble; this was removed thirdly through the incision made for the right lobe. This also seemed to be identical in its feel and consistency with the other two. Double drain tube put in."

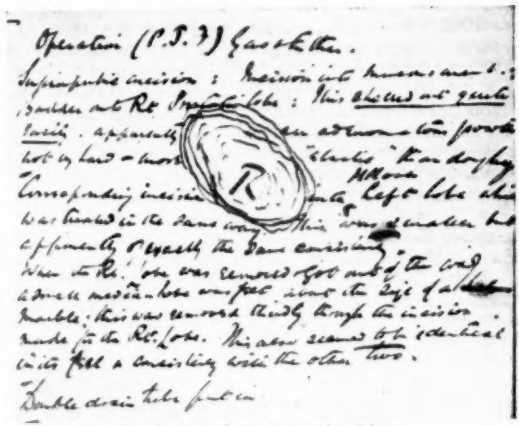

FIG. 3.—Extract from Operation Notes.

POST-OPERATION NOTES

"Passed *all* water naturally and *quite dry since three weeks and three days after operation*. Holds his water two and a half hours.

"Night two or three times.

"Had had 'gout' in ankles last week or two ago.

"April 22, 1912. Patient writes (82 years of age): 'I must say I am perfectly right in my urinary organs and for which I shall never be able to thank you enough.'

"April 1913. Died in the St. Pancras Infirmary from heart disease. The bladder and urethra preserved. (*Vide* specimen in St. Peter's Hospital.)"

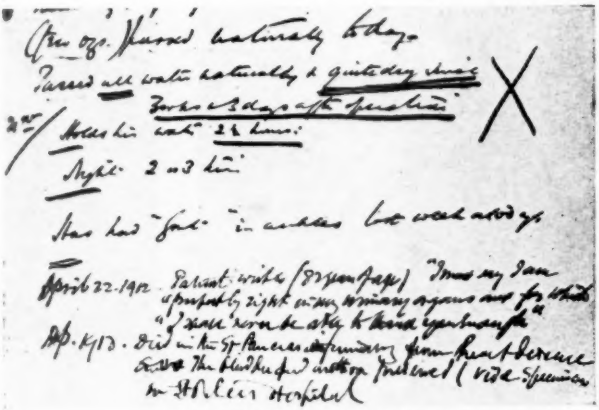

FIG. 4.—Post-operation Notes.

The sequence of events, then, in this remarkable story is as follows:

1900: Prostatectomy operation on John Thomas by Peter Freyer.

1913: Death of John Thomas: post-mortem examination and removal of pelvic organs to Freyer Collection of Prostates at St. Peter's.

1930: Discovery by Mr. Joly of organs labelled "J. T."

1956: My confirmation of Mr. Joly's story by finding notes of cases operated on by Freyer in 1900, fifty-six years previously.

There has been much controversy concerning the question whether or not Freyer was the first surgeon to carry out suprapubic prostatectomy successfully, but whatever views may be held about this, no one will deny that by his teaching and example Freyer effected a great improvement in the surgical treatment of prostatic obstruction, and it was because of his pre-eminence in this field that he was chosen as the first President of the newly-formed Section of Urology in 1920.

LORD HORDER

Sir Thomas Horder, later Lord Horder, was the second President of this Section.

I have chosen a photograph of Horder as a young man because his interest in urology began early in his career: in fact, it might be said that it was the urinary system which provided him with the key to the citadel of fame!

As a young physician he was called into consultation by the medical advisors to King Edward VII, who was thought to have sugar in his urine. Horder found that the diagnosis of glycosuria was incorrect. Above the bed of the royal patient he had noticed a number of bottles of patent medicines, and among them a popular remedy against rheumatism containing ingredients which he knew might give rise to a false positive reaction if the urine were tested for sugar by Fehling's method, then in general use. His Majesty King Edward VII was advised to abstain for a time from his patent medicines and the reducing substance in his urine promptly disappeared.

In the early nineteen twenties Horder was one of a small group of physicians who attended the meetings of this Section regularly and took an active part in its discussions. He was the second member of the Section to contribute a paper to the "Proceedings".

Horder's attendance at our meetings, and especially his presence in the Presidential Chair, provided an invaluable link with general medicine. In my view this was his special contribution to the developing life of our Section. Later on Horder became interested in so many movements, institutions and organizations that his early contacts with urology came to be overlooked, a fact on which Mr. Clifford Morson commented in a letter referring to Horder's obituary notice in the *British Medical Journal* (August 20, 1955). Mr. Morson mentioned Horder's share in the foundation of this Section, and added that even before this Section was formed Horder had expressed the view that the trend of development of urology would not be exclusively surgical.

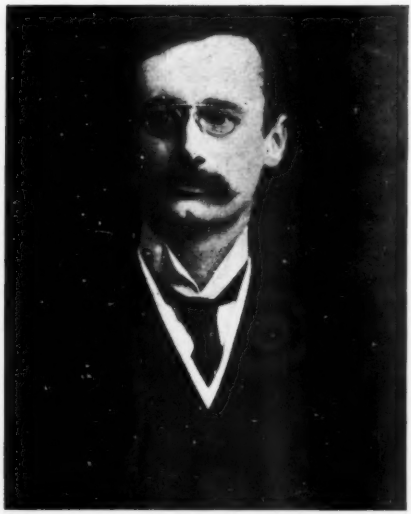

FIG. 5.—Lord Horder (as Sir Thomas Horder).

FIG. 6.—Sir John Thomson-Walker.

SIR JOHN THOMSON-WALKER

Sir John Thomson-Walker was the third President of the Section.

After the death of Sir Peter Freyer in 1921, Thomson-Walker occupied a position of undisputed supremacy in the world of urology for more than fifteen years. This was due, not to any high degree of originality in his scientific or clinical work, but to the fact that he improved and perfected the conceptions of his predecessors, and seemed to introduce a quality of excellence into all that he said or did.

I welcome the opportunity of recalling my impressions of Thomson-Walker because a year or two ago a urological surgeon at one of the big London teaching hospitals told me that he had referred to him in a lecture and found that even the registrars and assistants seemed to know very little about him. Yet it is less than twenty years since he died, and in his day his reputation was literally world-wide.

Sir John Thomson-Walker, both in dress and manner, was always "the perfect gentleman". He was tall and carried himself well. He was an upright man in every sense of the word. He was self-confident without being proud. He was well aware of his authoritative position but not in any way self-assertive. I remember a conversation during which reference was made by a patient to the leading urological surgeon of the day in the United States. Thomson-Walker remarked at once: "Of course I know him well: he is my opposite number in America." It sounded as if the King of the Old World were paying homage to the King of the New World!

Finally I must mention his industry and scholarship. I once asked him how he had managed in the midst of such a busy life to find time to keep himself up to date in pathology and other scientific subjects. He replied quite simply that his health had not been good and that he had not slept well at night, so had made a habit of doing an hour or two's study each morning before breakfast.

Sir Walter Langdon-Brown

Dr. Langdon-Brown, later to become Sir Walter Langdon-Brown, and Regius Professor of Medicine in the University of Cambridge, was the fourth President of this Section.

Langdon-Brown's presidency forged an invaluable link with scientific medicine and especially physiology.

The breadth of his vision and the variety of his interests is shown by the fact that he was elected President at different times of no less than four Sections of the Royal Society of Medicine, namely Urology, Therapeutics, History of Medicine and Endocrinology.

I met him first in 1929 in preparation for a combined discussion on urinary antiseptics between the Sections of Urology and Pathology. He was deputed to speak for the Section of Urology and I had been appointed in a similar way by the Section of Pathology. A few weeks before this meeting he invited me round one evening to his house in Cavendish Square so that we might agree on procedure. Naturally I was anxious to find out what he was going to say, and it transpired that he had the same attitude to me. But we soon came to terms. We both agreed that urinary antiseptics did no good anyhow! This, of course, was long before the days of sulphonamides or antibiotics: even before the days of the ketogenic diet.

After this I met Sir Walter Langdon-Brown on many occasions and came to know him well and to respect him greatly. He was a charming host with a great knowledge of good food and good wine, and a vast fund of anecdotes.

Phase of Restriction of Membership to Urological Surgeons

Sir Walter Langdon-Brown was President of this Section in the session 1923–24 and he was followed in succession by Mr. Cyril Nitch, Mr. Jocelyn Swan, Sir Girling Ball, Mr. Frank Kidd and Mr. Swift Joly. My impression is that during this period the control of the Section passed almost completely into the hands of urological surgeons.

It was, of course, natural that at this time most of the active members of this Section should have been surgeons, because it is they who have developed this specialty and added to our knowledge of the subject; but if you recall what I said about the first officers and early Presidents you will realize that the founders of this Section had a broader conception of the general scope of urology and at first, chiefly owing to the influence of Horder and Langdon-Brown, the medical aspects of urology were kept well to the fore. The attendance book shows that for the first four or five years of our existence a strong group of consulting physicians and a few pathologists attended the meetings of this Section regularly. Then we passed into a phase when the activities of this Section appeared to be of interest only to urological surgeons: others ceased to attend.

The gradual restriction of active membership of this Section to urological surgeons continued for a period of about twenty years, during which time physicians, radiologists and pathologists rarely attended our meetings. I can remember when it seemed almost as if *I* were enjoying an unopposed practice in pathology within this Section, a state of affairs which was neither good for me nor for the Section! However during the last three or four years this has gradually been put right and we now have a strong group of younger pathologists taking an active share in the life of the Section, especially at the clinico-pathological meetings.

Looking forward into the future, I venture to predict that the programme arranged for this Section in the coming session is likely to attract a more varied audience than in the past, and that it is not unlikely that an increasing number of physicians and even general practitioners may begin to return to the fold.

The reason why I anticipate a "come-back" of physicians is because some recent advances in urology have led to the discovery of hitherto undeveloped territories in medical know-

ledge where many others besides urologists may wish to stake out a claim. A good example is provided by cancer research. I will illustrate this by a recent personal experience.

A few weeks ago I had to travel to Italy to attend a committee meeting of the International Union against Cancer, at which representatives were present from thirty or forty different countries. We were a miscellaneous collection including University professors, whole-time research workers, clinicians, pathologists and administrators. We met in the new science buildings of the ancient university of Rome. The weather was very hot, the agenda was long, and we made slow progress. Towards the end of the third day my thoughts began to wander, and as I gazed absentmindedly at the distinguished company seated round the enormous table I began to ask myself which member of this international committee had contributed most to the advancement of our knowledge of cancer during the last few years. This was not a difficult question to answer. My eye fell at once on a member of the delegation from the United States, a surgeon known to most of you, a urologist, Charles Huggins. His researches into the pathology and treatment of cancer of the prostate are amongst the most outstanding contributions to the cancer problem made in recent years, and, as you know, they already have far-reaching implications in relation to general medicine and especially endocrinology; and we owe all this to a practising urological surgeon.

It is obvious that if discoveries such as these concerning the hormone control of cancer are being made by urologists, then it will not be long before the programme of the Section of Urology will be scanned with renewed interest by members of other Sections of this learned Society. For this reason we should be prepared for visitors and be ready to receive them.

Subsequent Presidents

Following Sir Walter Langdon-Brown there have been thirty-two Presidents of this Section, all of them surgeons.

I wish I could say something about each of the remaining deceased Presidents, because I am sure that in his day each one made his own special contribution to the life of this Section. But I have time only to speak of two more, and have chosen Mr. J. Swift Joly and Sir Henry Wade. I do not suggest for a moment that these did more than others. I chose them chiefly because I knew them both intimately and also because one, Swift Joly, was a pure urologist, whereas Henry Wade was a general surgeon with a special interest in urology.

Mr. J. Swift Joly

Mr. J. Swift Joly was the ninth President of this Section.

Swift Joly will always be remembered chiefly because of his researches into the pathology of calculus disease of the urinary tract. This was the subject of his Presidential Address to this Section and the theme of his monumental work "Stone and Calculus Disease of the Urinary Organs", published in 1929.

After his appointment to the Staff of St. Peter's, Joly confined his practice exclusively to urological surgery, but he had an immense store of learning in all sorts of subjects, was an entertaining conversationalist and possessed a quick Irish wit.

Swift Joly accomplished a great deal but was never in a hurry. One of his peculiar mannerisms was always to sign his letters "Yours in haste", which was perhaps in keeping with his name "Swift" Joly though not in keeping with his behaviour: in fact, if one met him anywhere he always seemed to have time for a leisurely chat. He loved a joke, especially if there was something a trifle whimsical or quixotic about it.

I have already mentioned that when I was appointed Pathologist to St. Peter's Hospital I found a collection of urinary calculi which were used for lectures to post-graduate students. Swift Joly knew more about these than anyone else, so I asked him to select those which he thought should be analysed chemically. Amongst the collection was a peculiar brownish oval stone about two inches in diameter which Joly said had been used for many years for teaching purposes but he knew nothing about its origin, though he assumed it was a vesical calculus. "This stone", he said, "must certainly be preserved", so I made a preliminary analysis of scrapings from the surface, and was surprised to find that these did not show the presence of any oxalates, uric acid, urates, cystin, phosphates or carbonates. Swift Joly also was much mystified by this, so we decided to bisect the stone and to submit one-half to an expert for complete chemical identification. I ought at this point to mention that when the stone was bisected we both noticed that its structure was uniform throughout and that there was no obvious nucleus or lamination and there were no concentric rings. Therefore, we were not surprised when a few days later the report arrived to say that this was not a urinary calculus but simply a big lump of plaster of Paris, thinly coated with varnish. It is still in the Museum of St. Peter's Hospital, now labelled "alleged calculus".

SIR HENRY WADE

Sir Henry Wade occupied the Presidential Chair in the session 1937–1938, and was the first urological consultant from North of the Tweed to be invited south for this purpose. He was the forerunner of other distinguished compatriots who are fortunately still with us—namely W. W. Galbraith, A. H. Jacobs and David Band.

Henry Wade was a skilful surgeon but also a very sound pathologist, and it is to this side of his character that I wish to pay my tribute both as pupil and friend.

It is now well known that operations which enucleate the prostate through its line of cleavage may result in the posterior lobe being left behind, though Sir Peter Freyer maintained at first that his operation removed the whole prostate gland. There was a good deal of controversy about this and Henry Wade became interested in the question during the two years at the beginning of his career when he worked in the Pathology Department of the Royal Infirmary at Edinburgh. It was natural therefore that when he subsequently came to London for postgraduate surgical experience he should visit St. Peter's Hospital to see for himself what Freyer was doing. He did so, and some years later in a communication to this Section he described how he had sat on a bench in the operating theatre at St. Peter's and watched Freyer swiftly and dextrously complete his prostate operation: after which Freyer brought the specimen across to where the visitors were sitting and demonstrated to his own satisfaction that he had removed the entire gland.

But Henry Wade was unconvinced.

Henry Wade returned to Edinburgh to study this question again. He cut whole sections of fifty operation specimens and made similar large slices through the prostatic bed from patients dying after prostatectomy operations. This left him in no doubt that the so-called hypertrophy of the prostate is in reality a limited hyperplasia of the more centrally placed prostatic glands. He proved that some of this may be left behind after enucleation.

Perhaps at the time it may have appeared to some as if this were an academic question only, but Henry Wade saw that it might have a bearing on the whole problem of the regeneration of prostatic tissue and on the possible site of origin of prostatic carcinoma. Looking back now into the past, to the great services rendered to this Section by my predecessors, I should like to pay my special tribute of affection to this former President hailing from North of the Tweed for his outstanding contributions both to urology and to pathology.

OTHER INFLUENCES BEHIND THE SCENES

So far in this tour "behind the scenes" I have referred only to the influence of Presidents, but I can also recall many secretaries, councillors, editorial and library representatives and others who by their loyal service helped to build up this Section to the strong position in which it is to-day. Fortunately most of them are still with us and for that reason disqualified from further mention at present.

Furthermore, to avoid any possible misunderstanding, I must explain that in this Presidential Address I have not attempted even to outline a serious history of this Section. All I have been trying to do so far is to entertain you with a gossipy sort of talk on some incidents behind the scenes, based on personal and accidental recollections.

THE UROLOGICAL PATIENT

In conclusion I am going to ask you to return to the back of the stage so that I may introduce to you a shadowy figure waiting for us unnoticed behind the scenes. This is the urological patient! I am recalling him now so that we may pay our tribute to him because it is my firm conviction that the chief incentive to the foundation of this Section was the pressing need of the urological patient. Moreover, all through the thirty-six years' history of this Section this anonymous individual has played a more important part in the development of urology than any President, Secretary, or Councillor. But for him we should not exist! In your name, as President of this Section, I now assure THE UNSEEN PATIENT that he will not be forgotten at any of our meetings, and whether our talk be grave or gay it will always be on his behalf.

We know, of course, that we come here to these meetings for many different reasons, such as to meet old friends, to enjoy each other's company and to receive instruction and edification. But deeper down, perhaps subconsciously, we come for the same reasons which inspired the Founders and original members of this Section, namely because we know that here in the fresh invigorating atmosphere of the public forum, we can discuss the urological patient objectively, without so much as a passing thought for hospital estimates or priorities or any such thing. It is a fine tradition. We have inherited this freedom from our predecessors. We must preserve it, both on the stage and behind the scenes, and hand it on unsullied to our successors.

[*November* 22, 1956]

THE following cases and specimens were shown:

Tuberculous Sinus following Nephrectomy.—Mr. E. W. RICHES.

Kidney with Double Pelvis Removed Ten Years after Transplantation of its Duplicated Ureters, Because of Hydronephrosis in Upper Segment.—Mr. ARTHUR JACOBS.

Caseous Tuberculosis in one Half of a Horseshoe Kidney.—Mr. J. H. CARVER.

Nephrocalcinosis. ? Rein-en-Éponge.—Mr. D. INNES WILLIAMS.

Granuloma of Kidney.—Mr. D. INNES WILLIAMS and Dr. R. C. B. PUGH.

Long-standing Vena Caval Obstruction and Hypernephroma.—Mr. J. C. ANGELL (for Mr. J. D. FERGUSSON).

A Fluid Renal Opacity.—Mr. MARCO CAINE.

Vesicocolic Fistula due to Diverticulitis.—Mr. N. SLADE (for Mr. ASHTON MILLER).

Bladder Stone with Glass Nucleus.—Mr. ALEX E. ROCHE.

Torsion Testis.—Mr. N. SLADE (for Mr. A. WILFRID ADAMS).

Tumour of Testicle—for Diagnosis.—Mr. DAVID WALLACE.

Carcinoma of the Urethra, Two Cases.—Mr. C. WIGGISHOFF (for Mr. A. W. BADENOCH).

Ectopic Ureter Draining into Vagina with Hypoplasia of Corresponding Kidney.—Mr. A. G. ELLERKER.

[*January* 24, 1957]

Ten-year Follow-up of Cases of Adenocarcinoma of the Kidney

By A. C. THACKRAY, M.A., M.D.

ABOUT ten years ago Mr. Griffiths and I analysed a series of cases of carcinoma of the kidney which had been seen at the Middlesex Hospital and associated wartime Sector hospitals during the preceding thirteen years (Griffiths and Thackray, 1949). We excluded from our series the transitional and squamous cell carcinomas arising in the renal pelvis and calyces, and carcinoma of the kidney as used here refers only to tumours arising from the renal tubules. The survival figures, as far as we could estimate them at that time, were as shown in Table I. We were agreeably surprised by these figures, the percentages surviving

TABLE I.—SURVIVAL RATE OF NEPHRECTOMY CASES

	Years since nephrectomy			
	One	Three	Five	Ten
Number surviving	44	24	16	4
Possible survivors	57	43	34	19
Percentage surviving	77	56	47	21

TABLE II.—PERCENTAGE SURVIVING

	Years since nephrectomy			
	One	Three	Five	Ten
Preliminary figures	72	58	48	20
Final figures ..	66	53	39	24

one, three, five and ten years being 77, 56, 47 and 21, which compare favourably with Priestley's three, five and ten year percentage survivals of 48, 38 and 27 for a large series of cases from the Mayo Clinic (Priestley, 1939). The number of survivors falls steadily from the time of operation to the ten-year limit of follow-up, with about a quarter of all patients dead within the year and about a quarter still alive at ten years. This great variation in survival time is well known; one patient may die with widespread secondaries after a few months, another may die with similar metastases after the lapse of several years, whilst occasionally apparent cures are seen. In our review of these cases we sought an explanation of these wide variations in survival and paid particular attention to any factors which we thought might influence the prognosis. We wanted to include as many cases as possible, particularly as the significance of the various factors considered had to be tested by reference to the follow-up figures, and therefore included all patients operated upon up to the time of writing. Consequently for the five-year follow-up little over half the cases were available for consideration, shown in Table I as possible survivors, and comparatively few for the ten-year figures. This survey of the ten-year follow-up series of cases is a review of the results of surgical treatment of carcinoma of the kidney. We should remind ourselves that only between two-thirds and three-quarters of all cases are in fact operated upon. Of the 80 cases in our series in which surgery was considered, only 60 were operable, an inoperability rate of 25%, quite comparable with the 28% given in the very large-scale study of these tumours at the B.A.U.S. meeting in Glasgow in 1951 (Riches, Griffiths and Thackray, 1951). Furthermore, patients are seen in the post-mortem room from time to time who have died from the effects of such carcinomas and in whom the diagnosis was never made during life.

The pathological section of our investigation was confined to those cases, 40 in number, for which microscopic sections of the tumours were available as well as the actual operation specimens or adequate descriptions of them. For this group the preliminary survival percentages are shown in Table II compared with the final percentages based on latest reports. At the time of our previous paper (1949) one or two of the cases included had been operated upon less than a year before whilst two other cases who had already survived five years could not be traced in the recent round-up and have had to be omitted from these figures. One had returned to his native Poland and we are still hoping for news of him. These changes have reduced the one-year survivals from 72% to 66%.

The pathological factors which may bear on the prognosis.—The prognosis for a patient from whom a malignant tumour has been surgically removed depends on whether the primary growth has been removed entire, on whether any metastases are already present, and, if so, how rapidly they will develop and prove fatal. From an examination of the removed tumour-bearing kidney we might hope to decide whether there was direct extension into surrounding tissues which were not removed, but it is difficult to assess this point retrospectively on the preserved specimen, and though the pathological reports may mention tumour reaching the surface of the kidney they rarely hint at whether the tumour extended to the limit of the perinephric fat removed. But from the fact of local recurrence being recorded in 9 of our 38 cases, we may take it that the primary growth is not always completely removed.

Features suggesting the likelihood of metastasis having already occurred are of obvious importance, presuming that no secondaries are clinically detectable at the time of operation. The size of the primary tumour might be expected to indicate the likelihood of metastases being present, but is, in fact, a very poor prognostic guide. Dividing these 38 tumours into equal numbers above and below the average of 3 in. diameter showed relatively little difference in survival rate. The same, incidentally, goes for the length of history. The patient who has survived the longest so far in our series, twenty years, had a three-year history and a tumour larger than the average; on the contrary, a patient who presented with paraplegia was found at post-mortem to have a circumscribed kidney tumour only 2 in. across, with no length of history as far as the urinary system was concerned, his only symptoms having been due to spine secondaries. From the size point of view the only patients who seem to do unusually well are those in whom small tumours are unexpectedly found in a kidney removed for some other condition, such as stone.

The regional lymph glands are removed together with the primary growth in operations for carcinoma in some situations such as the breast or bowel. A most important factor in the prognosis of a patient with breast cancer is whether the axillary glands are invaded. Our President's investigations into the significance of the lymphatic spread of bowel cancer are among the classics of pathology. Although the near-by lymph nodes may well be invaded in renal cancer they are not systematically removed. They were noted as involved and samples were sectioned in 6 of our cases, to which reference will be made later, but in the great majority of cases there was no mention of their condition and no conclusions can be drawn as to their significance in prognosis.

The renal tubules from which our tumours arise depend for their normal function on a copious blood supply, and the corresponding tumours seem to induce the formation of numerous and large vascular channels as they grow. The growth often invades these vascular sinuses and extends along them towards the main renal vein, eventually filling, blocking and distending it. The invading growth, often with a good deal of adherent thrombus, may extend out into the vena cava and may obstruct that vessel. Portions of the mass are liable to break off and lead to pulmonary embolism, sometimes during nephrectomy. The presence of tumour within the renal vein adversely affects the prognosis as shown in Table III. Note that despite invasion of the renal vein some cases still survive

TABLE III.—PERCENTAGE SURVIVING

five and even ten years. Where there was no mention of the state of the vein in the notes it was counted as free, so that the 37% incidence of renal invasion is a minimal figure.

Histological assessment of malignancy.

From the renal tubules two common types of tumour arise. Firstly, the well-known "hypernephroma" with its characteristic naked-eye appearance—golden areas and areas

of hæmorrhage—is composed of cells which are arranged in some semblance of tubules, the cells themselves being characteristically clear in the ordinary histological section since the lipoid and glycogen which they contain during life is dissolved out in the preparation of a paraffin section. This type is sometimes known as a clear cell carcinoma.

The second type is a papillary cystadenocarcinoma, which is composed of numerous cysts packed with cauliflower-like processes projecting from their walls. Though papillary in arrangement this tumour is unrelated to, though occasionally confused with, papillary growths of the transitional epithelium of the calyces or pelvis. These two types of tumour differ somewhat in behaviour, the hypernephroma having a greater propensity for blood spread with secondaries in the lung and often bones, and the papillary cystadenocarcinoma, which sometimes presents as multiple foci in the kidney, more often involving lymph nodes and liver. Despite these differences we found no significant difference in the overall survival rates for the two types.

In our original study, undoubtedly the single pathological feature of greatest prognostic significance proved to be the histological grade of malignancy. While Mr. Griffiths was extracting details from the patients' notes I settled down with the 40 sections and graded them. In grading a tumour the following points are considered: (1) The degree of differentiation or the extent to which the tumour cells are arranged either as tubules or in papillary cystic formation, the two types of tumour just described being considered together for the purpose of grading; the better the differentiation the lower the malignancy. (2) The uniformity or otherwise of the tumour cells; the greater the variation in size and staining the higher the malignancy. (3) The frequency of mitoses and hyperchromatic nuclei, features suggesting rapid growth. Taking all these points into consideration we arranged the tumours into three grades, Grade I tumours of low malignancy, Grade II of average and Grade III of high malignancy. There is no hard and fast dividing line between the grades which merge imperceptibly into one another, and there is no reason why we should choose three grades rather than four or two except convenience. The other point to stress is that the grade is a feature of the microscopic appearance of the tumour and no other factors such as size or presence of metastases are taken into consideration when grading.

Having graded our 40 tumours we correlated them with the follow-up details and found a quite satisfactory degree of agreement. Now that the cases, or 38 of them, have been followed up for the ten-year period the actual percentages have altered a little but the agreement remains good (Table IV). The percentage surviving falls steadily through the years in each grade and also falls steadily from Grade I to Grade III in each year. Of the group of 11 Grade III cases only 3 survived one year and there were no deaths between one and three years; one of the 11 survived five years and was still alive at ten years.

It is probably easier to picture the fate of these various patients by recording their years of post-operative survival (Fig. 1). The years after operation are marked out along the bottom, and lines, each representing a patient, run varying distances towards the right, corresponding to the number of years survived. With the exception of the 9 patients still alive at ten years the lifelines are terminated by a short vertical stroke indicating death. The area of black representing the sum of the years lived by the Grade I cases is strikingly larger than the black area for the Grade III cases, with the Grade II area of intermediate size. The survivors at ten years are 1 Grade III, 3 Grade II and 5 Grade I. Down the left side are a series of discs opposite the patients whose renal veins were invaded by tumour. There are only 3 of these in Grade I, 5 in Grade II and 6 in Grade III. Notice that the survival of the 3 Grade I cases with venous involvement, three, seven and over ten years, is considerably longer on the average than the Grade III vein-free cases.

The Grade III tumours grow quickly, invade the vein and infiltrate the surroundings, sometimes with quite short histories. With rare exceptions metastasis has occurred and secondaries are developing, even with quite small primaries, by the time they are operated upon. Death usually occurs within a year or two. At the very bottom of Fig. 1 we have a line reaching to the limit, a woman who had an undoubtedly Grade III tumour removed fifteen years ago and is alive and well to-day, without the help of radiotherapy before or after the operation. Either the tumour was removed before metastasis had occurred or she had well developed those powers of resistance to malignant tumour cells of which we know little or nothing. 3 of the Grade III cases with venous involvement also had invaded lymph nodes present, and of that trio the longest survival was six months.

The Grade II cases of average malignancy are more variable. 3 lived to ten years and 2, both with veins invaded, died within a week or two of operation. One of these was an old lady, then aged 70, who was strongly suspected of having a renal tumour but was not thought fit for operation. She returned seven years later with clot retention. This time her kidney tumour was removed but she died of coronary disease a week later.

The lines for the Grade I patients all extend at least two years, even those with venous involvement. Among them is a case where many invaded lymph nodes were seen when the

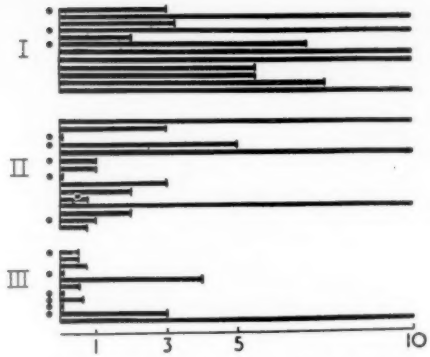

FIG. 1.—Post-operative survival in years.

kidney was removed, one being taken for section. Without further treatment she lived seven and a half years. Seeing how many of these Grade I lines reach to the ten-year limit and having seen how very regular was the histological appearance of some of the examples I showed you earlier, you may be forgiven for suspecting that the good results in Grade I are due to my having mixed in a number of simple adenomas with the low-grade carcinomas. I will admit that one of these cases was originally diagnosed as an adenoma, the shortest of the lines, for she died two years later from secondaries. The tumour was very large, measuring 8 in. × 7 in. × 3 in., so there may have been more malignant areas present. It is a rare type not corresponding to either of the two common types I mentioned; the tubules are very reminiscent of collecting tubules.

To counteract any tendency to suspect that there are some adenomas in the Grade I group, I have gone outside the limits of my title. This time the follow-up has been extended to fifteen years, and 3 of the ten-year survivors have died of recurrence at 14 years (Fig. 2).

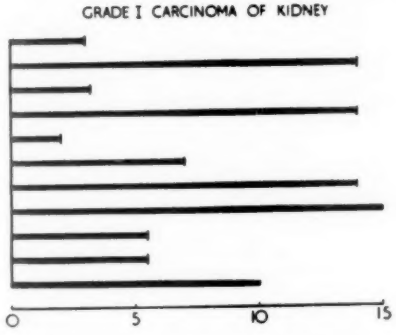

FIG. 2.—Post-operative survival in years.

One of these was a patient of Sir Gordon Gordon-Taylor's who had such striking invasion of the renal vein that a painting of the specimen was done. In these 3 cases it was noticeable that the eventual development of the metastases, which must have been present all along, corresponded with the onset of other forms of ill-health possibly lowering the powers of resistance; in one case genito-urinary tuberculosis, in another hypertensive heart failure.

Only 2 of this group of low-grade tumours are still living; one at a mere ten years and the other at twenty years. She had been troubled by a lump in her side for three years; the X-ray suggested a calcified mesenteric cyst but it proved to be a renal tumour. She has survived twenty years. Perhaps it was an adenoma. But we must be patient. At our last meeting a man was mentioned who at the age of 55 in 1929 had had a kidney tumour removed by Sir Gordon Gordon-Taylor after six months' hæmaturia. He next appeared many years later at St. Bartholomew's with a large solitary secondary in his clavicle, which was removed, twenty-four years after the original nephrectomy, when he was 79 years of age.

Grade I tumours, then, are slow growing, more or less circumscribed with no great tendency to massive invasion of the vein. Symptoms quite often are of long duration and tumours large when removed. They have nearly always metastasized, but the secondaries develop slowly and patients survive several years.

Thus we set out to see whether the pathological examination of the excised tumour-bearing kidney would help in prognosis, and suggested that what was required was some indication whether metastasis had already occurred and if so how long the secondaries would take to develop and prove fatal.

It appears that metastases are, unfortunately, very often present at the time of nephrectomy, particularly if the renal vein is invaded and the tumour is of high grade; and that the time the metastases take to develop and kill depends largely on the grade of malignancy.

By taking both the state of the vein and the grade of malignancy into consideration we can divide the cases into six categories, the survival rates for the best and worst of these being contrasted in Table V. These are, of course, only very rough guides to prognosis, to which

TABLE V.—PERCENTAGE SURVIVING

	Years since nephrectomy			
	One	Three	Five	Ten
Grade I Vein free	100	87	75	50
Grade III Vein invaded	17	17	0	0

exceptions occur; we have no control, for example, over deaths from other causes, whilst in a Grade III tumour whether or not metastasis has occurred before operation will make the difference between death in a year or so and a normal span of life.

Mr. E. W. Riches said that Dr. Thackray had given the ten-year survival figures collected from all the surgeons at the Middlesex Hospital over a long period of years. On a less ambitious scale Mr. Riches had been through his own personal series in order to determine the five-year survival. Out of 60 patients there were 42 operated upon five years or more ago, and of these 22 (52%) had actually survived for five years. 17 were in Grade I with 12 survivors (71%); 16 were in Grade II with 8 survivors (50%); 9 were in Grade III with 2 survivors (22%). In the large B.A.U.S. series, reported in 1951 (Riches, Griffiths and Thackray) the 5-year survival of all cases was about 33%; and figures were given to show how the prognosis became worse as the histological grade of malignancy became higher.

Another important factor in prognosis was invasion of the renal vein by growth, and in the previous series this had occurred in 29%. There was some correlation between histological grade and vein invasion for the vein was involved in 19% of Grade I cases, 28% of Grade II, and 48% of Grade III. In his own series the vein was involved in 15 out of 60 cases (25%). Of the possible five-year survivors 15 had involvement of the vein, and only 5 actually lived for five years.

There were bound to be anomalies in any attempt to assess prognosis, and it was only possible to give a general idea of what might happen to any particular patient; for example there was one man of 60 who had a Grade III tumour with involvement of the vein and invasion of the perinephric fat, who was alive and well eight years later. There were two others with Grade II tumours and involvement of the vein who were alive and well five and ten years respectively after operation; in their cases the tumours had been fixed, and they were each given a course of X-ray therapy before operation; he felt that this had been an influence in their survival. Wells (1954) had expressed a preference for pre-operative rather than post-operative irradiation; it was in the high-grade tumours with venous involvement that X-ray treatment had its best effect, and it was a pity that the grade and the state of the vein could not be known beforehand. Pre-operative X-ray treatment should certainly be given if there was any evidence of local fixity of the tumour. There were other factors affecting prognosis apart from the general condition and age of the patient. Invasion of lymph nodes was obviously an adverse factor, but it was remarkable how well they responded to post-operative X-ray treatment in some cases. The presence of a distant metastasis was evidence that blood-borne spread had occurred, but sometimes such a secondary deposit was single and isolated and occasionally it was amenable to surgical excision with the possibility of prolonged survival. There was little doubt, however, that the histological grade was the most important single factor in prognosis.

Professor L. N. Pyrah referred to the question of whether the grade of tumour was consistently the same in all parts of the tumour and also in the metastases; or, alternatively, if some tumours presented the microscopic picture of more than one grade? Every surgeon operating on large numbers of kidneys must have encountered the small to medium-size yellow cortical tumour which the pathologist sometimes reports as an active adenoma, or a low-grade hypernephroma, or even a latent carcinoma of the kidney.

If we accepted the fact that these cases were latent carcinomata or latent hypernephromata and included them in a series, it would weight the prognosis of the lower-grade tumours favourably; the real explanation might, however, be due to a marked difference in the biological behaviour of these latent cases from that of a definite kidney carcinoma. Was it possible to differentiate these two kinds from the pathological sections?

There was the possibility of removing isolated metastases resulting from a primary hypernephroma of the kidney, sometimes, in fact, before the primary tumour was clinically recognizable. The speaker had had one case in which the leg was amputated for a malignant growth which turned out to be a secondary to a hypernephroma; the left kidney containing the primary hypernephroma was subsequently removed and so far the patient was well. Another patient with a medium-sized hypernephroma of the right kidney was treated by nephrectomy; seven years later he was successfully operated on for a cerebral metastasis and he died after a further two years from a metastasis in the remaining kidney.

Professor D. F. Cappell asked about the foam cells shown in the papillary tumour of the renal cortex. He had seen other examples of this condition, heavily laden with foam cells and he wondered why these tumours collected foam cells within their stroma. Pathologists were interested in cholesterol in a variety of conditions. That these tumours have such striking collections of lipoid cells in the stroma might indicate that the renal cells from which one assumed they were derived had some definite function in this respect.

Secondly, he was much struck with the confirmation of what was precisely his own experience, viz. that it was impossible to give an accurate prognosis in the individual case. The tumour which was called Grade I was, on the average, more likely to have a good prognosis or to survive longer, but it was unsafe in any particular case to give a prognosis on the basis of involvement of renal veins.

Pathologists should endeavour to grade their tumours so that an accurate comparison could be made between one centre and another. Before that could be done, however, for the results to be worth-while there must be some agreed uniform standardization. Thanks to Dr. Cuthbert Dukes this had been done with bladder tumours, and there should be agreed standard criteria by which renal tumours would be graded on their histology.

Mr. Wilfrid Adams hoped a word could be said about dormancy in this sense: did we assume that a single Grawitz cell or microscopic clump, via the lung, seeded itself or was it the sole survivor of myriads? What factors in the patient explained the distinctive very late solitary metastasis of this nephroma? He wondered if Dr. Thackray could define the meaning of the old discarded term "hypernephroma".

Mr. A. W. Badenoch mentioned a male of 79 who was referred to the X-ray department at St. Bartholomew's Hospital by Mr. R. S. Murley with a large tumour in the right clavicular region which on biopsy was found to be an adenocarcinoma of the kidney. The right kidney had been removed twenty-four years before by Sir Gordon Gordon-Taylor, a retrograde pyelogram on the left kidney was quite normal.

X-ray therapy was non-effective. Mr. Murley removed the metastasis and the patient lived for ten months. This was the longest interval he knew between the removal of a renal adenocarcinoma and the development of a secondary. He had a man in his ward now who had the 11th left rib with a tumour removed at the Brompton Hospital in November 1952. Histologically the tumour was an adenocarcinoma of the kidney. On investigation a small filling defect caused by a tumour in the upper pole of the right kidney was revealed and a nephrectomy was performed in January 1953.

He remained perfectly well up to three months ago, when he developed backache due to a metastasis of the 5th lumbar vertebra, i.e. three years after removal of the secondary and primary growths.

If the spread of the tumour were assessed in conjunction with the histological grade one would arrive at a more accurate prognosis. Mr. Badenoch thought that if at operation it seemed that the whole of the tumour had not been removed, X-ray therapy should be given but prophylactic irradiation, other than to the renal fossa, did not seem practical.

Dr. Thackray, in reply, said that Professor Pyrah had asked whether the grading held good in all parts of the tumour. In a small percentage of cases there was a sharp difference in the grading in different areas of the growth; a careful look at the cut surface of the tumour might show well-defined and apparently encapsuled areas and other regions where the growth was obviously infiltrative. He had slides of tumours which were low-grade in part and elsewhere high-grade. The various grades of carcinoma merged into one another, Grade I carcinoma would merge into adenoma and the histological distinction between the two might be very difficult to make. A series of very small tumours discovered unexpectedly in kidneys removed for other reasons was being followed up. Certainly, in the literature, one or two large adenomas had been reported with the remark that the patient was well a year or two later. The report would have been of much greater value if it had waited twenty years.

He had no personal experience of secondaries being removed from the lungs and elsewhere. In reply to Professor Cappell, papillary cystic growths often had a good deal of hæmorrhage into the lumen, and the epithelial cells contained hæmosiderin. Though lipoid was often noted within the papillary processes he had no information about the mechanism by which it got there.

He agreed that it was very rash to give a definite prognosis in these cases, and could give no reason why groups of tumour cells should remain dormant in various sites for long periods. In reply to Mr. Wilfrid Adams he said that the term "hypernephroma" was much easier than "adenocarcinoma of the renal parenchyma". He hoped that they would get used to the term which Mr. Adams had suggested—"nephroma". The tumour was composed of renal epithelial cells and was comparable with hepatoma in the liver.

The Aberrant Renal Artery [*Synopsis*]

By F. T. Graves, M.S., F.R.C.S.

In 1953 the anatomy of the human intrarenal arteries was investigated in order to discover whether there was a constant pattern of these vessels. The arteries of post-mortem specimens were injected with a resin which subsequently solidified; the organic material was then removed by corrosion. The investigation showed that the distribution of the arteries within the kidney substance is constant and that upon this arterial basis the organ is divisible into five segments. It was also shown that there is no collateral circulation between these segments.

Although the initial work was done mainly as an aid to renal surgery, at the same time a study was made of the arteries of the renal pedicle, particularly those said to be "aberrant" arteries. Hitherto, a popular view has been that normally the kidney is supplied by a single renal artery which enters the hilum and that any additional artery entering the organ at one or other pole is necessarily an extra and aberrant source of supply to that provided by the main stem artery.

The investigation has included a study of more than seventy casts and sixty arteriograms. It has been found that in those cases where the main stem of the renal artery divides into the intrarenal arteries at the hilum, that is the "normal" arrangement, the artery to the lower segment frequently takes its origin from the main stem at a point more proximal than do any of the others. It was also found that when the renal pedicle consisted of more than one artery, the additional artery was one of the segmental arteries, most often to the apical or lower segments, whose origin was more proximal than usual.

The variations of the intrarenal arteries have been classified into Groups and Types (Graves, 1954, 1956):

Artery	Variations in the "normal" (division at the hilum)	Variations presenting as "aberrants": At the hilum	In the pedicle	From the aorta
Main stem	—	—	Early origin of divisions	Separate origin of divisions
Apical segment	Types 1, 2 and 4	—	Type IIIa	Types III b, c, and d
Lower segment	Type A arranged with other anterior segment arteries as in Groups 1, 2, and 3	Group 1 with long lower segment artery	Type B	Types C, D, E, and F

This table has been made for clarity and convenience. There is, in fact, no real difference between the variations of the so-called "normal kidney" and those of the apparently grossly abnormal kidney with four "aberrant" arteries. If the arteries of the renal pedicle are examined in conjunction with the intrarenal arteries and not as separate entities, then it becomes evident that the so-called aberrant or accessory arteries are really normal segmental arteries whose origin is more proximal than usual. This proximal origination accounts for many of the cases of multiple or "supernumerary" arteries of the renal pedicle.

Like the normal segments of the kidney, the segments supplied by "aberrant" arteries have no collateral circulation between their areas, so that ligation of such a vessel will result in necrosis of the area supplied.

Study of the embryology of the renal arteries as described by Felix (1912) provides an explanation for the variations of the segmental arteries. It is probable that those intrarenal arteries which have a proximal origin at the hilum or from the pedicle are the result of variation in the degeneration of the *rete arteriosum urogenitale*, whilst those which arise from the aorta are persistent mesonephric arteries.

In order to provide a clearer nomenclature, it is suggested that the "aberrant" artery in question should be given its name and type, as, for instance "The Lower Segment (aortic)

Artery," and that the words "aberrant" and "accessory" should be avoided, as they have little anatomical, surgical or descriptive value.

For further details and illustrations of "Aberrant Arteries" *see* Graves (1956).

Mr. E. W. Riches wondered how many times Mr. Graves had seen infarction after the lower polar artery had been divided. He thought that it must occur but presumably if there was no infection it did not matter. The only relevant specimen of which he knew was that illustrated by Ball and Evans (1932) of a septic infarction following ligation of a lower polar artery. It was easy to remove a constriction at the pelvi-ureteric junction by dividing the artery which appeared to produce it, whether it was the initial cause of the hydronephrosis or only a secondary factor, and they all had patients in whom the hydronephrosis had apparently been cured in this way. Since Mr. Graves had drawn attention to the distribution of the renal arteries he had been reluctant to divide an artery to the lower pole unless he was going to remove that pole at the same time. In doing a partial nephrectomy it might be possible to cut off the blood supply of the part one wished to resect by ligating the corresponding segmental artery; this might be safe for the apical or the inferior segmental artery but not for the posterior branch which supplied a large area of the upper and middle segments.

He was a little worried over the term "aberrant" or "accessory" artery which had been in use for such a long time; perhaps it should be called an "anomalous artery". If an aberrant artery was one which had an abnormal origin or entered the kidney in an abnormal position there were very few aberrant arteries connected with hydronephrosis; more often it was the inferior segmental artery which was involved.

REFERENCE

BALL, W. G., and EVANS, G. (1932) Diseases of the Kidney. London.

Mr. H. K. Vernon said that he agreed with Mr. Riches that if a polar artery were divided, an area of infarction occurred, but it did not matter. In a case of obstruction of the ureter by a lower pole artery, it was not stressed sufficiently that the obstruction was not at the uretero-pelvic junction. The obstruction occurred a little below the pelvi-ureteric junction, and the ureter was dilated between the latter and the obstruction. He had found that simple division and ligation of the artery was sufficient to relieve the basic symptoms and, in many cases, improve the hydronephrosis.

Mr. Wilfrid Adams described a case where five separate arteries supplied a little hypoplastic kidney in a woman of 80 years. It seemed to him to corroborate Mr. Graves' explanation of the normally developed system of segmental arteries in the ordinary mature kidney.

With regard to the aberrant artery he thought it explained the hydronephrosis in a substantial number of cases. There might be neuropathy in some, intrinsic pyelo-ureteric obstruction in others, but the mere division of the artery might cure. Division of the artery in a girl of 4 with a large hydronephrosis had allowed the pent-up urine to rush down the ureter, like water over a dam; it was most spectacular.

Another interesting point was the question of its influence as an end artery on the subsequent anatomy of the kidney. Certainly in this patient, twenty years later, the girl was normal and the pyelographic pattern perfectly symmetrical on the two sides! Was it really a terminal artery? Mr. Graves might have an explanation in the arteriolar network of Felix; if that were so, surely there would be dilatation of some of the tributaries. Mr. Graves did not say whether by his solvent there might be breaking off of the ulterior branches, in which case some of the network of the anastomosis might have preserved the lower pole thus explaining why there was no corresponding atrophy. It might also explain those cases of partial nephrectomy where ligation of the inferior segmental artery was still followed by bleeding which did not seem to harmonize with the segmental distribution which Mr. Graves had mentioned.

Mr. Toby Levitt referred to the associated distribution of the gonadal and adrenal vessels which were shown to be derived from the renal artery. He wondered whether Mr. Graves had had the opportunity of studying the co-ordination between the adrenal and gonadal complexes and the renal complex? It would be interesting from the surgical angle if he could institute an inquiry into the proportion of the blood supplied by the renal pedicle to the adrenals and the gonads.

A practical point was to what extent, in carrying out a nephrectomy, these rather important and useful structures were damaged. Could it be that nature in duplicating these organs had anticipated the possibility of surgical or other intervention?

Dr. C. G. Whiteside said that he had had some suspicion that the aberrant vessel was part of the normal tree. In the angiographic literature it was pointed out that where the renal pelvis was divided or doubled, an aberrant artery was very common. At the beginning of his series he thought it was true that a large number of cases of divided pelvis or double pelvis appeared to show aberrant arteries. From recent studies, however, he had had doubt about this because he had had several cases of double pelvis with only a single artery.

Mr. Graves, replying to the discussion, said that he would like to make two points clear. First, that the work which he had described had been done entirely in the laboratory; the facts could be checked by examination of the casts (a number of casts were demonstrated at the meeting) and the arteriograms which had been made to supplement and confirm the evidence obtained from the casts. Secondly, his paper was concerned only with the anatomy of the aberrant renal arteries, and he had not intended to raise or discuss the subject of hydronephrosis.

From the evidence produced by his experimental work, he was sure that if a segmental artery was ligated or divided then the area supplied by that artery would become ischæmic. He felt that it was unwise to leave ischæmic tissue present in the body and particularly in the kidney.

A surgeon had once told him that on one occasion when he had compressed a segmental artery at operation the area of the kidney involved had not changed colour as was usual, and he had asked for a possible explanation. Mr. Graves had suggested that this failure to change colour might be due to one of three causes: either the surgeon had not compressed the vessel for long enough or had compressed it incompletely; or, the lack of cyanosis might be due to a high oxygen content of the venous blood in the area. In the latter case, the venous blood in the area would continue to circulate to some extent, even after compression of the segmental artery, because unlike the arterial system, there was no segmental arrangement of the intrarenal veins which had a free anastomosis throughout the entire kidney. This free anastomosis probably accounted for the bleeding from the cut surface of the kidney which had been noted by Mr. Wilfrid Adams, after ligation of the segmental artery.

Mr. Graves then defended his own suggestion that the name "aberrant" should be avoided. The names "aberrant" and "accessory" were so often used loosely and implied an extra blood supply, which was not present. The word "aberrant" meant "*wandering from its normal course*". Scientifically this was not applicable as the artery was a normal segmental vessel which had retained its embryonic origin and furthermore, rather than being a vessel which had grown out abnormally, was a mesonephric artery which had not faded away. Finally, if an artery was in fact the lower segment artery, why not say so? It would make for a clearer understanding in publications and discussions.

In answer to Dr. Whiteside's question, Mr. Graves said that he had had no specimens in which the pelvis or ureter had been duplicated. He was at the moment trying to collect material to study the blood supply in cases such as these.

In answer to a Member's question, he said that the blood supply to the renal pelvis had been described by Douville and Hollinshead (1955).

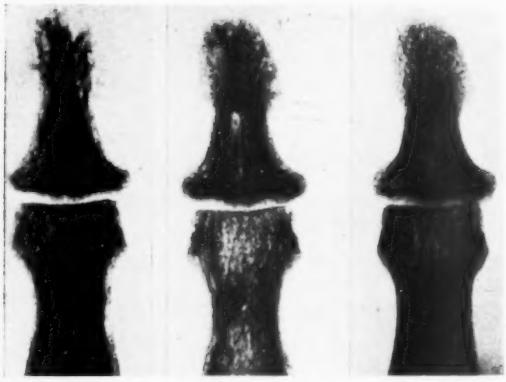
DISCUSSION ON GENERALIZED ACHES AND PAINS FROM METABOLIC BONE DISEASE

Dr. G. Alan Rose (University College Hospital): *Bone Pains in Steatorrhœa*

That a connexion exists between steatorrhœa and osteomalacia has been clear since the work of Parsons (1927) and of Bennett *et al.* (1932). In dealing with the individual patient, it may be obvious on clinical grounds that the patient is suffering from both of these conditions. Thus, he may present with the frequent, foul, frothy, offensive and bulky stools characteristic of steatorrhœa, and with gross bony deformities, and with tetany. In such a case the diagnosis will be easy, and is readily confirmed by biochemical and radiological investigations. The state of affairs may, however, be entirely different. The stools may have few or none of the characteristics mentioned. L. D., a patient recently described as "Case II" of Davies *et al.* (1956), had probably had steatorrhœa for very many years. She habitually used purgatives to obtain adequate bowel actions, and had never suffered from diarrhœa. This constipation may have been partly due in more recent years to a hypercalcæmia caused by a parathyroid adenoma, but this could not have been the whole explanation. V. M., a woman of 35, was found to have steatorrhœa at a time when she was having a bowel action once every three days. During the next ten years she developed frank diarrhœa, and finally osteomalacia. If the patient has a low intelligence quotient a history of diarrhœa may not be readily obtained. Patient L. B. was a girl of 17 when the diagnosis was made of steatorrhœa due to cœliac disease, with rickets and dwarfism. She had suffered from recurrent and severe attacks of diarrhœa from the age of 6 months; neither she nor her mother, however, worried much about these attacks, and her complaint on admission was that her knees were painful from banging one against the other (she had knock-knees). A patient with such an I.Q. may not appreciate the pallor of the stools, even if this is obvious to the doctor. Patient V. M. discovered by experience that a low fat diet tended to reduce her diarrhœa, when this finally developed. Others may find by trial and error that a low gluten diet helps them. Thus for various reasons, steatorrhœa may be present but not recognized.



The precise time relationships between the onset of steatorrhœa, and the onset of osteomalacia are not clear. Our present concept is that the steatorrhœa develops first, and is occult or overt. After a period of time, which is variable, but of the order of three to ten years, osteomalacia may develop. When this occurs, the steatorrhœa may still be occult. The onset of osteomalacia may be fairly sudden or it may be insidious. It is therefore possible that a patient with steatorrhœa may present only with the symptoms, either early or advanced, of osteomalacia. We may therefore hazard a guess that amongst the mass of patients presenting with general aches and pains, there will be some who are developing this syndrome. It is important to try and pick out these patients before they have developed crippling deformities, since therapy can prevent the deformities from occurring as well as curing the pains and other disabilities which precede them.

In our experience, patients with early osteomalacia due to steatorrhœa may often present with a certain pattern of symptoms whereby they may be recognized. The pains usually start in the lower half of the body, in the legs, thighs, pelvis or back. They are not sciatic in distribution and are frequently bilateral. The patient can usually clearly indicate that limb pains are between joints, and not in the joints themselves. After a period of time, the pains spread to other bones of the body, affecting the arms and shoulders. The bones may be tender to the touch. F. D., a woman of 58, had steatorrhœa with osteomalacia. The

lightest tap on her skull, long bones or thoracic cage caused her to wince. This may well suggest the diagnosis of "hysteria", but it should also suggest possible metabolic bone disease. The lower ribs may be tender. This was so in patients F. D., S. G., and M. Each of these patients stated that, on turning over in bed at night, she experienced pains in the lower ribs and in other bones. This was sufficiently distressing to make them arrange their bedding in ways calculated to prevent movements in their sleep. Muscular weakness is a feature frequently alluded to in various ways. A patient may develop a waddling gait, and this may be the first symptom recognized by him, or by his friends or relatives. Patient A. B., a woman with occult steatorrhœa, developed severe muscular weakness of the legs,

FIG. 1.—Radiograph of pelvis of a woman with steatorrhœa and osteomalacia of sudden onset, and with tetany. The bones are almost normal in shape, but show Looser zones in the pubic rami.

FIG. 3.

FIG. 2.—Radiographs of phalanges of a single finger of "Case II" of Davies, Dent and Willcox (1956). The patient had steatorrhœa and two parathyroid adenomata. A, before treatment (January 3, 1955) showing subperiosteal erosions. B, February 3, 1956, two months after removal of second adenoma. C, December 1956. The bones are now normal. This last follow-up radiograph was made after the paper of Davies, Dent and Willcox had gone to press. The others are taken from their paper, by kind permission.

FIG. 3.—Radiograph of lumbar vertebræ of "Case I" of Davies, Dent and Willcox (1956), reproduced by kind permission. Each vertebra is biconcave and shows two horizontal zones of osteosclerosis, between which is a less dense zone. The patient had steatorrhœa and radiological signs of hyperparathyroidism in the phalanges.

so that she was obliged to go up the stairs on all fours. Other patients have experienced feelings of "stiffness" in the legs on getting up, and which wear off with exercise. Others have felt unsteady on their legs, or unsure of themselves. These symptoms are not due to pain, or deformities, or general nutrition, and are reversed by treatment with vitamin D only. The other well-known symptoms of steatorrhœa may, of course, be present. There may for instance be nocturia due to delayed excretion of a water load. There may be a sore tongue, latent or overt tetany, or œdema.

The more fortunate patient who has developed osteomalacia due to steatorrhœa will be diagnosed before deformities occur. At this stage there may be no signs of old rickets, and the X-rays of the skeleton may appear entirely normal. Nevertheless, the diagnosis, when suspected, may be confirmed by a few simple tests. The urine calcium may be easily assessed in an out-patient department by the Sulkowitch test on any reasonably concentrated specimen of urine. The twenty-four-hour urine calcium provides the same information in a more precise manner. In the presence of normal renal function a very low urine calcium is suggestive of steatorrhœa. This may be so even if the plasma calcium is normal or high. Biochemical osteomalacia is demonstrated by the combination of a low plasma calcium and/or a low plasma phosphorus, with a raised plasma alkaline phosphatase. The diagnosis of steatorrhœa is confirmed by inspection of stools, by fat balance, glucose tolerance curve, water excretion test, blood count, and other tests.

In the less fortunate patient, there will be advanced bone changes before the diagnosis is made. These changes follow along certain now well-defined lines. If the osteomalacia is of relatively sudden onset, it will be characterized by the development of pseudofractures or "Umbauzonen" of Looser (1920). These zones of decalcification are considered by Dent and Hodson (1954) to occur in any relatively acute osteomalacia. Fig. 1 shows such pseudofractures in the otherwise apparently normal pelvis of a woman with steatorrhœa. If the osteomalacia is of more gradual onset, as has occurred in most of our cases, then the characteristic deformities of the chest, pelvis and legs will develop. Clinically relative trunk shortening will be found and X-rays will show that the bones are rarefied. The clavicle will droop, the tri-radiate pelvis will be seen, and there may be marked coxa vara. The X-rays of the lateral spine will show the biconcave "cod-fish" vertebræ, plus signs of decalcification. Each vertebra will have collapsed to the same extent as its neighbours. The osteomalacia of steatorrhœa may, as can occur in renal failure, be accompanied by radiological signs of secondary hyperparathyroidism. This has been described recently by Davies *et al.* (1956). One such sign is the "rugger-jersey spine" in which there are horizontal bands of sclerosis and porosis in each vertebra, as can be seen in Fig. 3. The subperiosteal erosions (Pugh, 1951) may be present. Fig. 2 shows the phalanges of a single finger of "Case II" of Davies *et al.* (1956) on three separate occasions. This patient had steatorrhœa and osteomalacia; subsequently she was presumed to have developed primary hyperparathyroidism following prolonged secondary hyperparathyroidism. These X-rays show the complete reformation of bone following removal of two parathyroid adenomata and massive vitamin-D therapy.

We now have good therapy for these cases of osteomalacia. A gluten-free diet is given if the patient has been shown to be gluten-sensitive and if he will be able to continue this as an out-patient. It is supplemented with folic acid, and with a form of vitamin D, in suitable dose. At present, we use calciferol, or dihydrotachysterol, or vitamin D_3. It is our hope that it will be possible to pick out more cases of osteomalacia with occult steatorrhœa who present with generalized aches and pains before they develop deformities, in order that early treatment will prevent these deformities from ever occurring.

Dr. F. H. Lumb (University College Hospital): *Pain in Renal Osteodystrophy*

Like steatorrhœa, chronic renal failure may be the cause underlying a variety of skeletal aches and pains which are diagnosed for long periods as fibrositis or rheumatism. It would be wrong to claim that renal osteodystrophy is a common cause of such symptoms, though this does not detract from the importance of its diagnosis. That this is so is shown by the very satisfactory response to treatment of patients with this condition, both in terms of prolongation of life, and of symptomatic relief. Once a renal cause for skeletal pain is suspected, a few simple observations and investigations go far towards establishing the

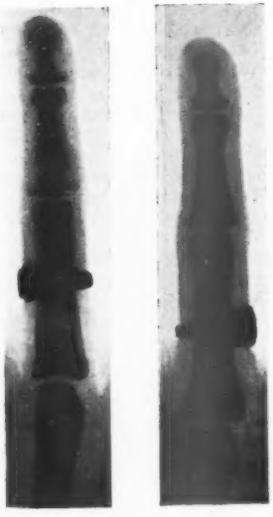
diagnosis. Furthermore, treatment other than that based on an attempt to correc the underlying biochemical disorder is of little value, failing to affect the discomfort an in-capacity, which gradually increase in severity. It would thus seem reasonable to atten t to define the main clinical characteristics of the renal osteodystrophies, as they often re nain for long unrecognized, even in patients already known to be suffering from chronic enal failure.

Various types of renal disease may be associated with bone abnormalities. In ge eral, predominantly glomerular failure, as in chronic nephritis, is associated with nit gen retention, and with raised serum phosphorus and low serum calcium levels. Bone pain may occur in such cases, and some show radiological evidence of secondary hyperparathyroidism, though not necessarily so. Tubular defects, as in the Fanconi syndrome, may also be associated with bone pain, though in these cases nitrogen retention may not be marked and the initial radiological changes are more those of osteomalacia (Albright and Reifenstein, 1948). Whatever the underlying renal disease, or type of bone change present, the symptoms tend to follow a common pattern. Also as the bony abnormality is due to biochemical disturbance and therefore generalized, it is hardly surprising that the patient's complaint should resemble those described in other forms of metabolic bone disease, as discussed by Professor Dent and Dr. Rose.

Both history and physical examination may greatly assist in the diagnosis of renal osteodystrophy. Obviously the clinical picture is greatly affected by the age of the patient, for in children chronic renal disease produces stunting of growth and deformity as its main skeletal manifestations, and such cases often present at orthopædic centres. Here, however, we are mainly concerned with adults, in whom bone pain is often the only presenting feature. Before discussing this symptom, however, another common aspect of the patients' disorder deserves mention. This concerns their previous contact with doctors and hospitals, where they have been seen on account of their increasing discomfort. In their attempts to obtain relief from pain they have often received treatment in various departments of physical medicine, orthopædics and sometimes psychiatry, not to mention general medical and other clinics. In one instance, a 35-year-old woman with a renal tubular defect and severe skeletal pain remained undiagnosed for six years, during which time she received a varied assortment of treatments which ranged from plaster casts to Evipan narcosis. The discovery of amino-aciduria in 1949, whilst she was undergoing neurological investigation, led to the diagnosis being established, and measures to correct her disturbed biochemical state have been associated with a most satisfactory symptomatic improvement. She is now in full-time employment as a shorthand typist.

In considering the case histories of those patients with renal osteodystrophy who have been under the care of Professor Dent at University College Hospital, the following features emerge. Pain, as mentioned previously, is the dominant symptom. As would be expected in a condition where the bones are generally affected, the pain is mainly referable to those parts of the skeleton which are subject to maximum stress and trauma. Thus pain affecting the lower limbs or lumbosacral region is a common complaint. It is often described as a severe, constant, nagging ache, difficult to alleviate, and of gradually increasing severity since its onset. It differs from sciatic pain in its usually bilateral distribution, and though it may be felt down the back of the thigh, it rarely spreads below the knee. Sometimes it is more definitely localized, coinciding under these circumstances with the presence of a stress fracture. Some patients notice marked bony tenderness, especially affecting the shins and ribs.

Characteristically, any increase in local stress is associated with an exacerbation of the pain. Almost always it is intensified by weight-bearing, and walking becomes more and more painful, resulting in restriction of activities and final immobility. Even the latter, however, may not give relief, as in the absence of treatment, the pain becomes more generalized, and even slight movements may become intolerable. Changing their position in bed is dreaded by some of these patients, who are wakened from their sleep by sudden movements, so much so that they not infequently go to considerable lengths to immobilize themselves by particular arrangements of pillows and bolsters. Similarly, if the ribs are affected, and stress fractures present, the patients will go to considerable lengths to suppress coughing on account of the discomfort which ensues.



Difficulty in walking may be due to the pain described, but occasionally seems to occur in the absence of the latter, or at least before pain is severe. The patient may describe a sensation of stiffness around the hip-joints and a feeling of uncertainty when on his feet. Such symptoms are usually associated with an obvious disorder of gait, best described as a waddling gait. One patient described a sensation of stiffness in the thighs, which limited walking in the absence of actual pain. Muscular weakness is often prominent in cases of renal osteodystrophy and may be extreme. It seems to be something more that the general lassitude of chronic uræmia and associated anæmia, and is a further reason why walking

may be difficult. As is well known, in those cases where potassium loss occurs consequent on a tubular lesion, periods of actual muscular paralysis may occur.

The combination of the pain, difficulty in walking, and muscular weakness described, should raise the diagnostic possibility of a renal osteodystrophy, and indicate the lines for further enquiry. The clinical picture described may long precede the malaise, vomiting and pruritus which signalize the terminal phase of renal failure, and these manifestations should not necessarily be expected. The osmotic diuresis, which, however, occurs at an earlier stage, gives rise to polyuria, nocturia and thirst, and such symptoms are worth enquiry.

FIG. 1.—Radiograph of the pelvis, showing stress fractures in the pubic rami of a patient suffering from chronic renal failure. The fractures healed with subsequent treatment.

A B

FIG. 2.

FIG. 3.

FIG. 2.—Radiographs of a finger, A before and B after treatment, showing the subperiosteal erosions associated with secondary hyperparathyroidism, in a case of chronic renal failure.

FIG. 3.—Radiograph of the spine, from the same patient as Fig. 2, showing the increased density of the upper and lower parts of the vertebræ—the "rugger-jersey" appearance.

They are especially marked in patients with tubular defects, even though in these conditions there may be little associated nitrogen retention. Such polyuria may occasionally determine an undue persistence of enuresis.

The past history may be helpful in various ways, especially if revealing a previous illness likely to have been responsible for chronic renal impairment. Long-standing renal dysfunction, present from childhood, may have produced disturbance of growth, the patient having been left behind by his younger siblings. The family history also repays investigation—similar cases in the patient's generation may indicate a Fanconi syndrome—whilst the affection of several generations with similar symptoms directs attention to such possibilities as polycystic disease of the kidneys.

The examination of these patients may afford further information of diagnostic value. Often they show an earthy pallor, in association with an anæmia, though in some cases well-marked brownish pigmentation may be present. This appearance is especially marked where there is tubular dysfunction and electrolyte loss and the pigmentation is essentially similar to that seen in chronic adrenal insufficiency, being well marked in the skin creases, over pressure areas and sometimes affecting mucous membranes. It is of interest to note that patients with renal osteodystrophy are not usually hypertensive, the blood pressure being often normal, or even low. This is perhaps important in the genesis of their disability, as marked skeletal lesions depend for their production on a renal failure of long standing, which is more likely to occur in the absence of hypertension and its complications.

If long-standing renal impairment has been present from childhood proportional dwarfism is the rule, though in some cases surviving puberty the limbs have been described as disproportionately long in comparison with the trunk—perhaps due to inhibition of epiphyseal fusion by some factor associated with chronic renal failure. Where tubular dysfunction presents in middle age, loss of height may be apparent. Further examination may disclose other suggestive features, such as marked bone tenderness, while such features as palpable polycystic kidneys would be of obvious diagnostic importance.

With a suggestive history and corroborative signs as described, the diagnosis may be further confirmed by simple investigations. A simple examination of the urine is of first importance. A dilute urine, containing protein and perhaps glucose, greatly increases the likelihood of a renal cause for vague skeletal pain. The Sulkowitch reaction requires further interpretation in the renal cases, where calcium excretion may be lowered, as in glomerular failure, or raised, as in states where tubular function is abnormal.

Radiography may be of value, though not necessarily so, as pain from bone involvement may be present before visible X-ray changes occur. Where there are clinical grounds for suspecting renal osteodystrophy, a negative X-ray does not abolish the necessity for further biochemical investigation. This does not imply, however, that radiography may not be of the greatest assistance (Dent and Hodson, 1954). Various different bone pictures may be seen, but, in general, the tubular defects as in the Fanconi syndrome are associated with a greater or lesser degree of skeletal rarefaction, and stress fractures are of great diagnostic importance (Fig. 1). Secondary hyperparathyroidism in glomerular failure is usually associated with visible radiological change (Fig. 2) and the interesting bony sclerosis affecting various parts of the skeleton being responsible for the "rugger-jersey" spine seems to be associated with this condition (Fig. 3) (Crawford *et al.*, 1954). Sometimes the X-rays may show a combination of these various changes, as would be expected from previous pathological studies (Gilmour, 1947; Follis and Jackson, 1943; Follis, 1950).

The recognition of renal osteodystrophy in patients with suggestive symptoms mainly depends on the possibility being borne in mind. Confirmation of the diagnosis is not difficult, and is rewarded by the excellent symptomatic response which may follow such measures as large but cautious doses of vitamin D and the correction of an associated acidosis. The diagnosis deserves consideration in all cases where pain of skeletal origin is not explicable on other grounds.

Professor C. E. Dent (University College Hospital): ***Pain in Some Metabolic Bone Diseases Not Due to Steatorrhœa or Renal Failure***

Before describing further types of adult bone disease, I will review briefly our general experience of all types at University College Hospital during the last five years. During this period our metabolic ward has been functioning and nearly all the cases I will mention have been admitted there and have been very thoroughly investigated. This data is summarized in Table I. It will be seen that, apart from steatorrhœa and the various forms of renal

TABLE I.—CASES OF METABOLIC BONE DISEASE (ADULTS) STUDIED IN THE LAST FIVE YEARS IN WHICH THE MAIN COMPLAINT WAS OF GENERALIZED ACHES AND PAINS

Senile osteoporosis	innumerable	all		

failure which have been already discussed by Drs. Rose and Lumb, we have also studied some metabolic bone diseases due to several other causes. The most common is probably that usually described under the name "vitamin-D resistant" osteomalacia. This condition is also associated with a renal-tubule leak for phosphate with few, if any, other signs of renal dysfunction. This group is certainly heterogeneous (Dent and Harris, 1956). Our 3 cases of vitamin-D deficiency require commenting upon. It is hardly possible to believe that this can occur in adults in this country since adult requirements are so small and the general level of nutrition adequate enough. For the same reasons, but with reference to the U.S.A., Albright and Reifenstein (1948) have stated "The authors are cognizant of no single case of osteomalacia in the United States due to simple vitamin-D lack. . . ." However, we have no doubts about the authenticity of our 3 cases and as all of them had reasonable worldly means but suffered only from curious ideas about food, further cases could presumably occur anywhere, even (perhaps especially) in the U.S.A. One of these cases will be mentioned in more detail below: the diet of another with brief clinical details has been described by our dietitian (Hill, 1956) and a brief reference to the third has been made by McCance (1953). As to the other diseases, the bone disease complications of ureterosigmoidostomy and of primary hyperparathyroidism are now well known. Although Table I is made out in the hope of giving some idea of frequency of incidence in the various kinds of bone disease, it is, of course, very inaccurate in this respect, as, apart from their small numbers, there is considerable selection in submitting patients to us.

It will be seen from Table I that the general symptomatology of the further bone diseases I am now introducing is similar to that described by Dr. Rose and Dr. Lumb for the special cases of steatorrhœa and renal dysfunction. Indeed, as far as the particular bone manifestations are concerned there may be no difference at all. However, associated additional findings in the history and clinical examination may be diagnostic. Note especially that in a small proportion of cases the skeletal X-rays appeared quite normal. Some

of these had very severe symptoms. The X-ray changes of the further cases shown in the bracket in Table I, when present, were usually indistinguishable from those in steatorrhœa and renal failure (Figs. 1 and 2A, B). An interesting additional point can, however, be made,

FIG. 1.—Pelvis of a patient suffering from one of the so-called "vitamin-D resistant" forms of osteomalacia. There are Looser zones in both ischiopubic rami and a further small one on the inner rim of the pelvis opposite the right femoral head. The patient was severely crippled by the pain but fortunately was diagnosed before symptoms had been present for long: there is therefore not much deformity. The clinical history of this patient was described by Rose (1956).

A B

FIG. 2.—Index finger of a patient suffering from osteomalacia associated with neurofibromatosis. In A, taken before treatment with vitamin D began, gross erosion of the terminal phalanx is visible and also subperiosteal erosions in the mid-phalanx, both of which we now interpret as being due to secondary hyperparathyroidism, a rare feature in this form of osteomalacia. In B we see the beginning of reformation of the phalanx after some months' treatment with vitamin D. This patient had also developed an osteoclastoma in her maxilla, which is a further sign of hyperparathyroidism.

namely that mixed osteomalacic and hyperparathyroid changes were comparatively uncommon in any of the ætiologies shown in Table I except in the case of renal-glomerular failure, when they were usually present together. The importance of the plasma biochemistry is well shown. It is mainly by this means that the cases have been diagnosed in the first place. I have also added to Table I three other kinds of bone disease which may also present in somewhat similar ways, although the symptoms are usually less generalized. Unfortunately our treatment for these is much less satisfactory.

Perhaps it would be simpler now to stress the clinical resemblance to steatorrhœa and renal disease, shown by one of these further causes of osteomalacia, by describing the relevant case history:

Mrs. L. R. A housewife, aged 46, referred to me by Dr. Cedric Shaw for investigation of "a great variety of skeletal and muscular pains coupled with increasing lassitude and embellished by a multiplicity of symptoms relevant to every single one of her visceral systems". Dr. Shaw added that she was clearly a very hysterical type of person and that no definite physical signs could be elicited apart from tenderness over the whole thoracic spine and a flinching whenever her abdomen was palpated. There was obvious dramatization and a long history of marital disharmony. X-rays, B.M.R., E.S.R. and full blood count were normal but, "as an afterthought", Dr. Shaw had determinations done of her plasma calcium, phosphorus and phosphatase levels. These showed abnormalities which suggested the possibility of metabolic bone disease being present.

On admission to the metabolic ward we fully confirmed the presence of plasma abnormalities. Her calcium was 8·8 mg./100 ml.; phosphorus 1·8 mg./100 ml.; alkaline phosphatase 20 units (K–A). Other electrolyte levels and blood tests gave normal results. Renal function was normal but urine calcium excretion averaged only about 20 mg./24 hours. Her bone X-rays and fat balance were normal.

Her history was interesting. It began with pain in her left hip twelve years previously: this was treated with heat and massage, but after a brief improvement pains returned and spread also to the right hip. She was otherwise fairly well till two to three years ago, when aches and pains began in other parts—arms, hands, thighs, ankles, chest, and the whole of the spine. Her bones became tender to touch and she suffered particularly from chest pain, especially when turning over in bed at night. To avoid being awakened by involuntary movements during sleep she had had to arrange her bed with bolsters on either side of her. She slept flat on her back in the groove thus formed. Nevertheless, on waking she felt as if she had been "beaten all over". It took her about an hour to get dressed. Her pains prevented her from going shopping or walking freely. She had noted muscular weakness, especially on going upstairs, when she needed to pull herself up by the banisters.

Our diagnosis on the basis of history, clinical and biochemical findings (and in spite of the normal X-rays) was of osteomalacia, but we were much puzzled as to its ætiology; but further study of her history revealed that although she ate well, and indeed looked very well nourished, she had always rigorously avoided fatty foods such as margarine, eggs, milk, oily fishes, &c., and had also avoided exposure to the sun in recent years. We estimated that her chosen diet had contained less than 20 units daily of vitamin D. Our suspicion that her bone disease was due to defective oral intake was subsequently fully confirmed by our studies of her metabolic and clinical changes before and after small oral doses of vitamin D. She is now almost symptom free, although still as peculiar as ever mentally.

Discussion

I hope that by now the point Drs. Rose, Lumb and I are trying to make has been made clear. It is that many cases of metabolic bone disease for which there is excellent treatment may in adults (the equivalent children's diseases usually present first with visible deformity) present with generalized aches and pains, usually rather vaguely localized and without any other obvious clinical features. These patients may be severely disabled, and although the diseases are all uncommon, they are gratifying to diagnose and treat. The problem therefore remaining is the very difficult one of picking out the one or two patients with metabolic bone disease (especially those without gross deformity or body disproportion) from the hundreds of others who also have aches and pains for other reasons. I can only suggest the following course of action as being practicable, as well as reasonably likely to succeed.

In the first place the clinical evolution common to all these cases should be very closely studied and remembered, bearing especially in mind the grave danger that the whole thing may appear to be entirely psychological. If the history is suggestive, and there will be many such cases, I think the urine should be tested routinely for the presence of protein (to pick out the renal cases) and for calcium with the Sulkowitch reagent (to pick out the low calcium excretions of many forms of osteomalacia). In both these cases the problem of urine concentration must be borne in mind for a very dilute urine cannot be properly tested and it is worth getting the patient to return with a morning specimen if necessary. (It is usually sufficient to look at it and only test specimens that appear reasonably yellow.) A case of severe renal damage will, of course, be unable to pass a strongly yellow urine, which in itself should arouse suspicion and be specially looked for. If there is still anything suspicious about the patient's history and preliminary urine tests, then further skeletal X-rays should be done, as well as blood tests, along the lines previously described (Dent, 1956), namely with respect to the plasma calcium, phosphorus, phospatase, bicarbonate and urea levels, and urine calcium output. If any of these are definitely abnormal, full and thorough investigation is justified and will not be too much of a burden since only a very small number of patients will survive this sorting and they will nearly all be genuine cases for whom we can do a great deal by medical treatment.

The treatment of these cases may sound surprisingly simple. It mainly comprises vitamin D with or without alkalis. There are serious dangers, however, of wrong dosage, the

required amounts varying considerably from case to case. Patients receiving treatment must therefore be carefully supervised. There is sufficient in the literature already about the treatment of steatorrhœa and of renal-tubular osteomalacia (Albright and Reifenstein, 1948). The renal-glomerular cases are more difficult and are not adequately covered as yet. We have considerable unpublished work on this subject which awaits longer follow-up of our cases. The treatment of so-called "vitamin-D resistant" ones has been reviewed recently by Dent and Harris (1956). There is still some doubt as to whether all the cases can, as we ourselves believe, be cured; and indeed Brailsford (1952) has described a case of typical osteomalacia that could not be cured with vitamin D, coining for it the new name of "osteogenesis exhausta". We have not yet come across such a case ourselves.

This review does not include all known causes of metabolic bone disease. Many interesting further examples such as that, for instance, following partial gastrectomy (Pyrah and Smith, 1956), or chronic liver disease (Atkinson *et al.*, 1956), or neurofibromatosis (Swan, 1954) have been briefly described already or are currently being further investigated. We have deliberately made no mention of other endocrine disorders such as Cushing's syndrome, acromegaly or eunuchoidism, all of which may present occasionally with pain due to bone disease. There is usually, however, in these cases much to take note of that would lead the patient to be first referred to an endocrinologist or general physician. Our attempt in this symposium was to describe cases very likely to be referred for treatment to Physical Medicine departments in view of the fact that the associated features which could lead to a correct diagnosis may require considerable looking for, and are never obvious at sight.

SUMMARY

(1) Osteomalacia may be a cause of severe, vaguely localized, generalized aches and pains in a patient not otherwise presenting notable clinical signs. While osteomalacia of a particular ætiology may be rare, there are many different ætiologies which together provide us with a moderate number of cases.

(2) An attempt has been made to define more closely the clinical features of osteomalacia. The history may sometimes be characteristic and the X-ray signs often pathognomonic and accompanied by the signs considered specific for hyperparathyroidism.

(3) Whatever the ætiology, the clinical signs and skeletal X-rays may be indistinguishable.

(4) The existence of occult forms of renal failure and steatorrhœa presenting only as osteomalacia is stressed.

(5) In all these cases the bone disorder and associated symptoms can be cured independently of the progress of the renal or other disease.

(6) Rough methods are suggested for distinguishing these cases from the large number of other patients with aches and pains.

The Ætiology of Fibroids

By PERCY MALPAS, F.R.C.S., F.R.C.O.G.

ALTHOUGH fibroids are the commonest of tumours, many aspects of their origin, their growth and their multiplication are still obscure. Largely this is due to the congruity between their structure and that of the tissues in which they grow. All the same, any explanation of their origin can only be based upon this congruity, or in other words their cause must be sought among the circumstances or conditions existing within the uterus itself; for whatever general factors may be concerned—such as age, childlessness, race, hormonal and growth factors—the immediate origin and structure of every fibroid is contingent on conditions obtaining in the local or intra-uterine causal field. This general principle was set out by Aristotle in the treatise "On the Parts of Animals". Discussing the nature of causation in biological phenomena Aristotle drew a sharp distinction between what he called hypothetical necessity and absolute necessity, defining absolute necessity as "such necessity as exists between substances and their inherent properties and characters". It is with the absolute cause of fibroids, that is their interpretation in terms of the structure and dynamics of the myometrium, that the present paper is concerned.

Exception may be taken to calling these tumours fibroids. The reason is that the term is a convenient and non-committal label which does not prejudge the issue. To call them myomas or fibromyomas is to beg the question, at all events in the present context, for the hypothesis to be proposed and considered is that these tumours are not true neoplasms, and that they arise and grow as the result of unresolved stresses in the myometrium.

The material falls into four sections: first the distribution patterns of fibroids, next the internal structure of established fibroids, next the evidence for the potentiality of stresses in the normal myometrium, lastly the structure of seedling fibroids.

THE DISTRIBUTION PATTERNS OF FIBROIDS

Provided that no one of a set of multiple fibroids is too large, their distribution in the uterus conforms to one of two general patterns. The reason for excluding any tumours much larger than a golf ball is that then the patterns become too complicated to analyse.

In the first and less important type of distribution, small fibroids, seldom more than 2 cm. in diameter, are scattered irregularly over the surface of the uterus. The distribution does not conform to any regular pattern. These tumours seldom grow to any size. This is shown by the frequency with which they are discovered accidentally when the uterus is removed for some other reason in women of 40 years or more.

The second type of distribution is the more important, not only for its theoretical bearing, but also because the tumours in this type undergo progressive growth and progressive multiplication. Almost invariably one fibroid in the set or pattern is larger than the rest. Its usual site is in the median sagittal plane of the uterus at the junction of the middle and inner thirds of the muscle wall, at a level roughly corresponding to the junction of fundus and body. This position corresponds to an interface between two zones of the myometrium. For convenience this largest tumour will be called "the dominant fibroid" in the following description.

The dominant fibroid is surrounded at varying distances by smaller tumours. These latter decrease in size as their distance from the dominant increases. Also the space between the secondary tumours themselves tends to increase with their distance from the dominant tumour (Fig. 1).

If it is assumed that the largest or dominant tumour is the oldest in the set, the progressive

decrease in size of the secondary tumours suggests that in some way or other their origin is contingent upon the presence of the dominant tumour. How could this arise? Possibly for this reason, that as a fibroid grows a considerable tension is set up both in the tumour itself and in the enveloping myometrium. This pressure is evidenced by the way the cut surface of a fibroid becomes convex, by the way that fibroids shell themselves out when bisected during the course of a myomectomy, by the force required to push a partially extruded fibroid back into its bed after it has been partially mobilized by an incision through its capsule immediately after a hysterectomy. This pressure sets up counter-pressures wherever any resistance is met with, and at the points where pressure and counter-pressure become equalized, energy is liberated and a condition of localized stress is set up. The situation is very similar to that obtaining in a crankshaft. Usually the secondary tumours are situated below the dominant tumour, along a line between it and the cervix, and the explanation of this pattern may be that the pressure exerted by the dominant tumour is more likely to meet a counter-pressure from below because of the relative fixity of the lower part of the uterus.

According to such a view fibroids are self-propagating tumours, that is to say that the presence of one fibroid induces the growth of others. There is some clinical evidence bearing on the problem. It is common to find a single symptomless fibroid in a young woman, and quite reasonably such a tumour may be left alone in the hope of pregnancy. Often it stays single and stationary in size for a year or so, and then fairly quickly fresh fibroids appear in an increasingly rapid succession, until at the inevitable operation the uterus is found stuffed with small secondary tumours, so many indeed that a hysterectomy usually proves necessary. The multiplication of the tumours follows a geometric curve, as indeed would be expected if the fibroids are self-inducing. That the small subperitoneal tumours remain small and isolated may be because of their position on a free surface where secondary stresses are not set up. Submucous and intraligamentary tumours likewise have a tendency to remain single.

FIG. 1.—Chains of fibroids in median vertical plane. Dominant tumour showing spiral structure, more marked in its outer half. Note diminishing size of secondary tumours and the increasing distance between them.

FIG. 2.—Two subperitoneal fibroids, 1 to 2 cm. across. Tumour on left shows linear mode of spread.

THE INTERNAL STRUCTURE OF FIBROIDS

Fibroids do not develop in a centrifugal manner from a central nucleus. Their usual spherical shape is solely due to their compression by the surrounding myometrium. Their true form is that of an irregular spiral with a varying number of secondary offshoots. This is shown by simple inspection of the cut surface of any soft fibroid with well-marked whorls but even more clearly by dissecting a fibroid under a dissecting microscope so as to separate the whorls, when the spiral shape becomes very evident. The spirals are usually more defined in the outer or peritoneal half of the tumour. Again the primitive shape is seen quite clearly in many of the small subperitoneal tumours which are less subject to compression (Fig. 2). In other words fibroids grow in a linear manner, a mode of growth most consistent with the view that their shape is determined by stresses in their structure. The almost constant occurrence of secondary nodules budding off the main tumour suggests that a dominant tumour induces secondary tumours not only at a distance but also locally. Certainly the

offshoots are not simple extensions of the primary tumour. Indeed their attachment to the dominant tumour may be quite tenuous.

Knots in wood are the resultants of stresses set up in growing tissues. The pattern exhibited by a knot in a piece of wood certainly bears a superficial resemblance to a fibroid, and if, indeed, a motto were wanted a saying of William Blake would be appropriate: "I can look at a knot in a piece of wood till I am frightened at it."

The Origin of Fibroids

When we consider the origin of the earliest seedling, it seems reasonable to assume that the seedling develops from causes similar to those which determine its continued growth. At all events such an assumption is certainly economical. To examine it entails, first, a consideration whether the potentiality of internal stresses exists within the myometrium as compared with plain muscle elsewhere in the body; and second, an examination of the microscopic structure of the seedling fibroid.

The Structure of the Myometrium

The myometrium is not homogeneous, but exhibits two sorts of differentiation. To begin with, its component muscle bundles are not straight but are disposed as a system of interlacing spirals. This is a consequence of the shape of the uterus. The uterus is an irregular solid, and in all irregular solids the lines of force along which the muscle bundles lie are not straight but geodetic—the shortest distance between any two points being a spiral curve. Because the bulk of the myometrium is composed of such interlacing spirals a low power magnification gives the fallacious appearance of an undifferentiated feltwork. Similar considerations indeed apply to the heart muscle, the heart too being best regarded as an irregular solid. The general problems of the structure of such tissues have been discussed by D'Arcy Thompson (1942) in "Growth and Form", and Shearer, in 1953, has drawn attention to the geodetics of the uterus.

Now in any system of interlacing spirals, there is a greater potentiality of internal stresses than obtains in tissues in which the muscle fibres are arranged in simple sheets at right angles one to the other, as is the case in the alimentary tract, with the exception of parts of the œsophagus, the stomach and the duodenum; by the way, these latter parts of the alimentary tract are almost the only sites in which the rare extragenital myomas appear.

Besides a spiral differentiation the myometrium is also divided into zones. While the zonal arrangement varies a good deal in definition it is common enough to be significant (Fig. 3).

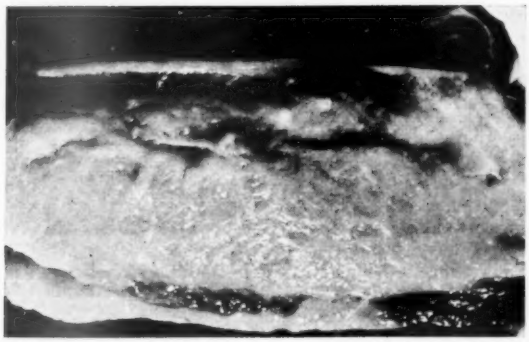

FIG. 3.—Enlarged photograph of whole thickness section of normal uterus (peritoneal surface uppermost). Note narrow outer zone and groove between middle and inner zones and "arcade" arrangement of bundles of inner zone, more noticeable on left.

It is more pronounced in the uteri of older women. The outermost zone, some 2 to 5 mm. thick, is dense. In it the muscle bundles are disposed symmetrically and mainly as a longitudinal sheet, the spiral disposition being less marked than obtains deeper from the surface. It is in this outer or cortical zone that the non-progressive subperitoneal fibroids occur.

The middle and inner zones constitute the bulk of the myometrium. They are separated by an interface in which run the main intra-uterine branches of the uterine artery and often this interface is marked in a cut surface by a narrow groove. The middle zone is the denser

of the two, in the inner zone the spiral disposition of the muscle bundles is more prominent (Fig. 4).

It is in the interface or partition between the middle and inner zones that a fibroid usually first appears, as indeed would be expected to be the case if an internal stress is its cause.

So far then there is some evidence from the heterogeneity of the uterus that the potentiality of internal stresses exists, but it may be asked what bearing this could have on the genesis of a seedling fibroid. An explanation could be that when a normal uterus contracts, as it does throughout pregnancy and to a lesser extent during every menstrual cycle, energy is liberated and under normal circumstances is expended in a change in shape of the organ. If for some reason or other, no change of shape is possible, by reason for instance of disuse changes in the myometrium, or increased viscosity in the matrix of the muscle spirals, or limitation of the uterine mobility by inflammatory appendage disease or endometriosis, the unresolved energy must be dissipated by the production of localized stresses, stresses which induce a local tissue reaction determining the appearance of a seedling fibroid. Before puberty and after the menopause, at those periods when the uterus is quiescent, fibroids never develop; after the menopause existing fibroids cease to grow. Furthermore fibroids seldom make their first appearance late in the reproductive period of life. In this regard the work of Fletcher Shaw and others on the histology of chronic metritis may well be relevant. For that matter in cases of pure hypertrophy of the uterus, which may weigh as much as 10 oz., fibroids are seldom encountered, perhaps because the internal structure of these uteri is normal. The viscosity and semi-fluid nature of the tissues are very apparent when an unstained fresh section of a fibroid and the surrounding myometrium is examined under a low power. Fixed and stained sections, necessary as they are, fail to show their plasticity.

FIG. 4.—Dominant fibroid, size of pea, in median vertical plane between middle and inner zones. Rough semicircle of seedlings to outer side. Outer zone of myometrium very well defined.

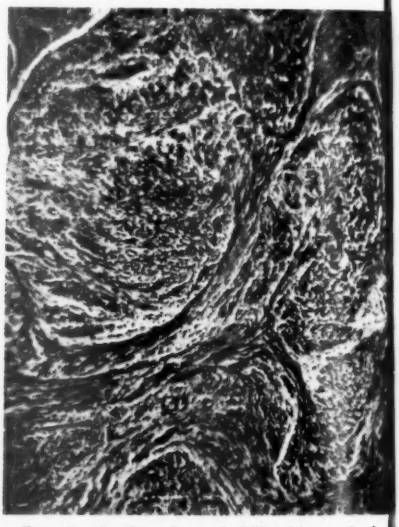

FIG. 5.—Section through "fibroid area", showing spiral bundles of myometrium enclosing and merging with seedling. Low power.

THE MICROSCOPIC APPEARANCES OF SEEDLING FIBROIDS

Two features of the structure of seedling fibroids have a bearing on the present issue. The one is their spiral structure, a point already discussed (Fig. 5). The other is their lack of any capsule, the encapsulation of larger fibroids being a secondary phenomenon. Willis (1953) states that "the usual view that myomas are encapsulated needs revision, for while it may be true of large tumours, it certainly does not apply to many small ones. Minute myomas, even when apparently well circumscribed to the naked eye, are often not sharply separable from the surrounding muscle microscopically". So true is this observation that it is often difficult to say where the normal myometrium ends and a fibroid begins, certainly by a microscopical examination. At the base of the seedling there is a gradual transition from one to the other, the muscle bundles showing an increasing distortion as they near the tumours and the cells

themselves progressively changing from the normal to the more primitive forms in the growing points of the seedling (Fig. 6).

FIG. 6.—Small intramural fibroid with extension into myometrium at 2 o'clock. Encapsulation of extension incomplete.

SUMMARY

There is some evidence to support the view that the origin, growth and propagation of fibroids can be interpreted as the result of unresolved myometrial stresses. The hypothesis certainly saves some, if not all, of the appearances without reference to any of the general factors usually invoked. This is not to say that such general factors are without significance. For instance, part of the answer to the genesis of fibroids is to be sought in the reasons why fibroids are at least three times as common in coloured women. Nevertheless, whatever the role of the general causes, the intimate structure and distribution patterns of fibroids can only be explained in terms of occurrences within the uterus itself.

Finally one general conclusion seems important, that fibroids are not neoplasms in the ordinarily accepted sense of the term, but local reactions arising in a tissue with a unique dynamic structure and one which is often subjected to long phases of physiological disuse.

Habitual Abortion

By V. B. GREEN-ARMYTAGE, M.D., F.R.C.P., F.R.C.S., F.R.C.O.G.

The Institute of Obstetrics and Gynæcology, Hammersmith Hospital

IN 1938, Malpas postulated that the chances of a woman having a full-term baby after 3 abortions was 27% only. In 1953, Swyer and Daley contested this and stated that the chances were 50%. Professor McClure Browne and the present writer think that there exists a hard core of cases of abortion which are due to congenital weakness or acquired trauma of the fibromuscular ring at the junction of the lower uterine segment and the anatomical internal os. The trauma may be due to the passage of a large baby, large dilators, or the faulty application of forceps, and results in herniation of the conceptus with quick, painless and complete expulsion of the fœtus—a condition that will recur again and again according to the degree of damage present.

In 1950, Lash and Lash devised an operation when the defect was in the anterior segment of the cervix—which must be very rare. In 1954 Shirodkar described his operation using fascial strips or nylon tape to encircle and constrict the cervical canal at the level of the internal os (Shirodkar, 1955). At the Institute we have simplified this technique by using one or two filaments of nylon, size 7.

In the non-pregnant patient, the condition of insufficiency at the internal os is considered to exist if (1) The patient has had 2 or 3 abortions, quick, painless and complete, with or

without a history of trauma. (2) A No. 4 Hegar dilator can be passed with ease and without pain through the cervical canal into the uterine cavity. (3) A cervicogram demonstrates the dilated canal—using a small finger stall firmly attached above the rubber cone of a Lipiodol syringe.

In the pregnant patient, often being seen for the first time, the criteria are: (*a*) The previous history. (*b*) A patulous external os which admits the finger almost to the internal os, soft and flabby.

The author has done seven of these modified Shirodkar operations: Three have gone to full term and been confined—two by Cæsarean section and one naturally. One[1] is in her 38th week and is particularly interesting as she was first seen in her 17th week after rupture of the membranes. One is in her 15th week and is worth recording as she had her second Shirodkar operation at the 12th week of pregnancy. One is in her 12th week. One has not conceived.

The operation must not be undertaken lightly, but if the indications exist, there are three essentials in the technique. (These were demonstrated by means of a coloured film.) (1) The needle must take a bite of the anterior surface of the cervix. (2) The nylon must be knotted in the incision on the posterior surface of the cervix. (3) The Macewen hernia needle or Reverdin needle must be blunt.

Unless otherwise indicated, Cæsarean section is not necessary.

If the ligature is seen before or during labour, all that is needed is to grasp the knot ends as they protrude from the posterior incision and cut the nylon filament. In such a case, if and when more children are desired, the operation must be repeated.

The Problem of the Trans-cervical Fracture [*Abridged*]

By DENYS WAINWRIGHT, F.R.C.S.Ed.

THE trans-cervical fracture of the femur continues to present a challenge to orthopædic surgeons, and increasing longevity makes it even more important that we should be able to offer the patient of 55 or 60, who sustains this injury, at least ten years of comfortable activity.

A recent study of the blood supply of the femoral head (Hulth, 1956), using a new angiographic technique in which opaque fluid is injected directly into the osseous tissue of the head, has shown that synovial bridges containing blood vessels remain intact even when gross displacement of the fracture occurs. This is particularly true of the inferior retinacular vessels which are not so closely related to the under-surface of the neck of the femur. Although it is probable that a good deal of the vascular change occurs at the time of the accident, preservation of these precarious life-lines of the femoral head must depend to some extent on careful handling of the patient after the accident. Early immobilization and correction of the deformity will prevent kinking of the vessels, and gradual reduction of the fracture by traction is less likely to damage the blood supply of the head than the often vigorous traction and rotation manœuvres which are sometimes necessary to secure an accurate reduction. Such a reduction is essential if internal fixation is to be successful.

The difficulties which are experienced from time to time in fully reducing these fractures by manipulation have in our experience been overcome by gradually reducing the fracture using a modified form of Russell traction—the traction being applied by means of a Steinmann pin through the upper end of the tibia. An upward pull from the outer side of the pin will gradually correct the external rotation deformity. Internal fixation of the fracture is postponed until full reduction has been obtained with the additional advantage that the operation can be performed at a convenient time. It is in many cases possible, by increasing the traction, to slightly over-correct the deformity, allowing the femoral head to tilt over into a coxa valga position, until the fracture resembles an abduction type. If in this position the fracture is then immobilized with a Smith-Petersen pin, or a type of blade plate, inserted well below the great trochanter in a fairly vertical direction as far as the sub-chondral region of the head, we have established the optimum mechanical position for union to take place. Immobilization of the fracture in any degree of coxa vara imposes an almost insuperable strain at the fracture site, with inevitable delay in union.

Sub-capital fractures and fractures with more or less vertical fracture line in which the blood supply is very likely to be severely damaged must be kept especially stable. Immobilization must be such that stability is maintained even after creeping substitution of any necrotic bone has begun. In the belief that in such cases complete immobilization can best be achieved by transfixing the head, we have, in a small number of cases, driven the nail through the head about ¼ in. into the acetabulum (King, 1939). Provided the weight-bearing portion of the acetabulum is avoided and the pin is not driven through the upper part of the femoral head, where it is likely to devitalize the outer third of the head, penetration of the head causes surprisingly little disability and the pin can be left in position for many months until radiological evidence of bony union is present.

In short, it is suggested that in the younger age group where the operation is not being performed as a life-saving measure or merely to ease nursing difficulties the transcervical fracture should be handled carefully, should be reduced gradually until it is slightly over-corrected, and if possible immobilized with a Smith-Petersen pin inserted in a fairly vertical direction; and that there is a place for complete transfixion of the head in the high fracture with a small fracture angle.

Causes of failure.—Provided the fracture unites, many of these patients will be able to contend with a localized area of necrosis of the head. It is pseudarthrosis which is responsible for most disability following this fracture.

The recognition of the early signs of failure and the beginning of non-union implies a careful follow-up, with X-rays repeated at intervals of a few weeks.

a) Primary instability.—These are cases in which the pin breaks loose within the first few weeks and these failures are usually due to technical errors and are much less frequent in experienced hands. When, as sometimes happens, the failure is due to inability to reduce the fracture, then I believe the treatment likely to give the highest percentage of reasonably good results is a displacement osteotomy of the McMurray type.

(*b*) *Secondary instability.*—Here the pin slowly ploughs its way through a more or less avascular head many months after the original operation. Osteotomy in these cases will provide reasonable stability but if the head is avascular union of the fracture cannot be expected. In such cases complete replacement of the dead head by a prosthesis will probably give a higher percentage of good results. If a reasonable amount of femoral neck is present, if the prosthesis is inserted in an almost vertical direction, if the patient is fairly light and is not expected to lead a very active life, a prosthesis of the Judet type can be expected to succeed. If, on the other hand, we are faced with complete non-union and little of the femoral neck is preserved, then a larger type of metallic prosthesis is indicated.

(*c*) *Late osteo-arthritic changes.*—Many of these patients do develop localized areas of necrosis of the hip with marked osteo-arthritic changes. These do not necessarily progress, nor cause much disability. In other cases, particularly those associated with an increasing coxa vara, the symptoms become progressively worse. In this particular age group the choice must lie between some type of arthroplasty and osteotomy. In my opinion a displacement osteotomy using internal fixation is likely to give the better long-term results.

HULTH, A. (1956) *Acta chir. scand.* Suppl. 214.
KING, T. (1939) *Brit. J. Surg.*, **26**, 721.

Mr. R. C. F. Catterall showed a film on "Chemopallidectomy" by kind permission of its originator, **Dr. Irving S. Cooper** of New York. The procedure was used in the treatment of Parkinsonism, athetosis and other conditions where it was believed that the essential lesion lay in the globus pallidus region. After some success with the very difficult operation of ligation of the anterior choroidal artery, Dr. Cooper's present method was to pass a brain cannula into the globus pallidus and, after a preliminary test injection of local anæsthetic, to inject alcohol.

The results illustrated were dramatic in the extreme and appeared to be permanent. Tremor disappeared completely in the contralateral limbs and the power of co-ordination returned. Good results were obtained by Dr. Cooper in about 70% of cases. Mr. Catterall and subsequent speakers stressed that other neuro-surgeons had not yet produced comparable results, the difficulty apparently lying in the exact localization of the globus pallidus.

The Relief of Pain in Paget's Disease (Osteitis Deformans)
[Abridged]

By ROY H. MAUDSLEY, F.R.C.S.

PAIN has been a common feature of osteitis deformans since first described by Sir James Paget in 1877. He wrote ". . . in earlier periods, and sometimes through all its course, the disease is attended with pains in the affected bones, pains widely various in severity and variously described as rheumatic, gouty or neuralgic, not especially nocturnal or periodical . . .". In eighty years little has been added to this description.

Many patients with Paget's disease also have osteoarthritis in the lumbar spine and hips, and some of their pain is attributable to this. It is the constant boring pain which bears so little relationship to other forms of limb pain that I wish to consider. The disappointment with treatment is reflected in the numerous methods tried and largely abandoned. The success attending the relief of unusual pain in the limb in causalgia and Sudeck's atrophy, by blocking of the autonomic nervous pathways, suggested a trial of this for Paget's disease. The technique adopted was that of epidural anæsthesia.

Epidural anæsthesia.—The susceptibility of nerve fibres to anæsthetic solutions varies according to their calibre and medullation. Thus a fairly selective anæsthesia can be obtained if a weak solution is used. This is capable of affecting autonomic and some afferent pain fibres, which are of small calibre and either non-medullated or only thinly medullated, but will not affect the thicker afferent and efferent somatic fibres.

Though it is not known how or where the pain in Paget's disease originates, nor which fibres are responsible for its transmission, epidural anæsthesia affords a ready access to the smaller somatic afferent fibres known to convey some pain impulses, and to the autonomic fibres, also a possible pain pathway.

The spread of anæsthetic fluid within the epidural space is believed to be wide, as shown by radiographs after the epidural injection of Myodil. This may well be an asset in making exact localization less important. The epidural space lies between the walls of the spinal canal and the dura mater, and is continuous laterally with the intervertebral foramina. This space is traversed by the spinal nerves, covered by a sheath of dura mater.

Technique.—The patient lies in the lateral position with the painful limb uppermost. The interspace between the 1st and 2nd lumbar spinous processes is used. Under local anæsthesia

the spinal needle is passed into the interspinous ligament. The stilette is withdrawn and replaced by a 20 ml. syringe with 0·5% Xylocaine. As the needle is moved on with the thumb gently pressing on the plunger, a decreased resistance is felt as the needle enters the epidural space. The syringe is removed and the end of the needle is observed, to exclude a spinal tap, after which 10–20 ml. of the Xylocaine is injected.

Clinical trial and results.—10 patients suffering from pain in Paget's disease have been treated by epidural blocks over the last five years. Each had had pain in the pelvis or lower limbs for a period from several weeks to several years. The blocks were repeated when necessary, to enable the patient to remain in comfort.

In most cases there was immediate relief of pain, though not always complete, lasting from a few days to a few weeks, after which the pain recurred, but in some instances at a reduced level. Further injections again relieved the pain for varying intervals. Failures to relieve were thought to have been due to selection of a patient with predominantly osteoarthritic symptoms and possibly to injections outside the spinal canal. Two patients had spinal taps and had temporary spinal anæsthesia, though still with relief of pain.

Discussion.—The mode of action is uncertain. If one believes in a sympathetic reflex with afferent and efferent neurones, then it may act on the afferent fibres carrying pain impulses; or it might act on the efferent fibres modifying the vascular state of the limb.

In none of my cases was a sympathectomy offered since the pain was controlled by these blocks.

It is difficult to explain the long pain-free intervals following injection with local anæsthetic, but a similar variation exists after sympathetic blocks for causalgia, Sudeck's atrophy, &c.

Summary.—A preliminary report is made on a simple and effective procedure in the relief of pain in Paget's disease. The technique and the clinical trial and results are discussed.

Hydrocortisone in Tennis Elbow—A Controlled Series [*Abridged*]

By R. A. J. Baily, M.B., F.R.C.S., and B. H. Brock, M.B., F.R.C.S.

Any consideration of the treatment of tennis elbow must raise the question of its pathology and ætiology. A study of the literature reveals considerable variation of opinion, and Cyriax (1936) lists no less than twenty-six different pathologies described by various authors.

To summarize his conclusions and those of subsequent authors, the following alternatives appear to be best supported by factual evidence:

Extra-articular.—(*a*) A tear of the extensor origin with or without periostitis. (*b*) A degenerative lesion of the extensor origin. (*c*) Inflammation of the underlying bursa of Osgood.

Intra-articular.—Nipping of a synovial fringe in the radio-humeral joint.

The literature has been reviewed, and on balance the evidence is in favour of an extra-articular degenerative lesion associated with strain of the extensor muscles, but a synovial lesion may exist in some cases.

Treatment.—In 1953, Hollander described the use of hydrocortisone (compound F) in intra- and extra-articular joint lesions, and found it beneficial in tennis elbow. In this country Cyriax and Troisier (1953), Murley (1954), Quinn and Binks (1954), and Crisp and Kendall (1955) have reported favourably on its use. In a controlled series, Freeland and Gribble (1954) found little difference in the effect of hydrocortisone from 5% procaine, but the small numbers make the result somewhat inconclusive.

The purpose of the present series is to assess the specific effect of hydrocortisone as distinct from the mechanical effect of fluid injection into the affected area.

Material.—In all, 40 patients were treated, of whom 16 were male and 24 female, the average age being 45·5 years. In 10 patients (25%), there was a history of trauma, usually a direct blow on the epicondyle.

In 10 cases associated complaints of pain, with or without stiffness, of the neck and shoulder were noticed at some time, but in all cases the relief of symptoms by procaine injection into the tender area was made a criterion of diagnosis, and such associated symptoms were regarded as incidental.

Method.—The series was divided into two random groups, A and B, by selection of alternate patients. Group B was treated by the injection of 1–3 ml. of 2% procaine into the tender area, followed by manipulation by Mills' manœuvre. Group A received exactly similar treatment but the additional injection of 25 mg. (1 ml.) of hydrocortisone acetate.

The injections were all carried out by one of us (B. H. B.), while the other (R. A. J. B.), who was unaware which treatment had been given, examined the patients at one week, three weeks and two months after treatment.

Where symptoms were unchanged after three weeks a course of physiotherapy was instituted (Renotin ionization, heat and deep massage), and in 8 cases still unrelieved after two months a second injection of hydrocortisone was given.

The results were assessed at the end of two months, and the results of those patients who received a second injection are given separately below. 9 patients were followed up for less than one month owing to non-attendance.

Results.—The results have been graded as *cured*—relieved of all symptoms, *improved*—with slight symptoms on heavy use and/or persistence of tenderness, *unchanged* and *worse* (Table I).

TABLE I

Treatment	Cured	Improved	Unchanged	Worse
Group A				
Hydrocortisone and 2% procaine	10 (50%)	4 (20%)	5 (25%)	1 (5%)
Group B				
2% procaine	5 (25%)	5 (25%)	10 (50%)	—
Totals	15 (37·5%)	9 (22·5%)	15 (37·5%)	1 (2·5%)

Of the hydrocortisone group, 14 (70%) were cured or improved as compared with 10 (50%) of the control group. 5 (25%) of the hydrocortisone group were unchanged and 10 (50%) of the controls. The 1 patient who was worse was a very unstable personality seeking compensation for a supposed industrial injury.

An exacerbation of symptoms for twenty-four to forty-eight hours occurred in 10 (25%) patients. Of these, 5 were in Group A and 5 in Group B, their eventual results being 7 cured, 2 unchanged and 1 worse.

In 8 patients whose symptoms were unchanged at the end of two months, a second injection of hydrocortisone was given. Of these, 2 were in Group A and 6 in Group B. The results of this further injection were 3 cured, 3 improved, and 2 unchanged.

In 2 patients of the hydrocortisone group and 5 of the controls early relief of symptoms was followed by relapse, confirming the findings of others that the effect of hydrocortisone, as of other treatments, may be only temporary.

Of the 9 patients who attended for less than a month, 4 were cured, 2 improved, and 3 unchanged when last seen.

In addition to the above findings, the results were analysed in relation to age, history of trauma, length of history, the presence of associated symptoms in the neck and shoulder, and the presence or absence of previous treatment. None of these factors showed any significant effect on the pattern of the results.

Discussion.—Tennis elbow is a self-limiting condition whose natural course is rarely longer than eighteen months. Any assessment of treatment must therefore take into consideration the time factor.

The results of this series, although the numbers are small, confirm that hydrocortisone is effective in the treatment of tennis elbow, and that its action may be distinguished from the mechanical distension of tissues by fluid injection. Although relapse may occur, the use of hydrocortisone allows a higher proportion of successful results than other conservative measures within a limited period of time. The relief of symptoms has in many cases been dramatic. In those cases where recurrence has followed initial relief, or where one injection has proved ineffective, a second injection is frequently successful.

We are indebted to Mr. K. H. Pridie, Mr. A. L. Eyre-Brook, Mr. H. K. Lucas and Mr. M. P. McCormack for permission to investigate patients under their care.

Section of Dermatology

President—Louis Forman, M.D., F.R.C.P.

[*January* 17, 1957]

Presentation of Diploma of Honorary Membership of the Section to Sir Archibald Gray

The President: I have a gratifying duty to perform which I know will give us all much pleasure. At the last meeting we elected Sir Archibald Gray as an Honorary Member of this Section, the highest honour which we can bestow upon any of our own Members or other dermatologists. Sir Archibald Gray has been a Member of the Section for forty-six years; he has held all the offices in the Section and he is our Senior Past President. Most of us have grown up under his guidance and this is therefore a very pleasant domestic ceremony.

Sir Archibald has been recognized and honoured in fields wider than our specialty but his active interest in dermatology and in our Section has been maintained. I have very much pleasure in presenting him with the Diploma of Honorary Membership with the hope that we shall enjoy his companionship here for many years to come.

Sir Archibald Gray: It is very kind of you to honour me in this way. My colleagues on so many occasions have done me so much honour that I scarcely know how to reply. I feel I cannot say more than to thank you very sincerely for your kindness.

CASES

Sarcoidosis with Skin Lesions Simulating Necrobiosis Lipoidica.—P. F. Borrie, M.R.C.P.

History.—A housewife, now aged 49, developed a fever in 1949 and was in hospital for three months. Examination at that time revealed right iridocyclitis, generalized superficial lymphadenitis but no other abnormal physical signs. During her stay in hospital she developed a transient left facial palsy and left hemiparesis and a localized thrombophlebitis in a vein on the left wrist.

Investigations.—Hæmoglobin 48%. W.B.C. count, normal total and differential. E.S.R. 10 mm. in the hour (Westergren). Plasma protein normal total and differential. X-rays of chest and extremities normal. Urine normal. Liver biopsy normal.

She made a steady recovery and her general health has since remained good. The iridocyclitis, however, persisted and progressed to uveitis and phthisis bulbi. The eye was removed in April 1956, histological examination showing sarcoidosis.

In July 1955 a non-irritant eruption appeared on both shins. Shortly after this superficial ulceration occurred in two small areas on the right shin taking seven months to heal. A month ago the eruption began to spread and fresh ulceration appeared.

The past and family histories are not relevant.

On examination.—On the front of both shins and the sides of the calves there is a patchy telangiectatic erythema. On the right shin there are two areas of depigmentation and atrophy, as well as a few superficial ulcers 0·5 cm. in diameter. There are also multiple, circular, discrete patches on the sides of the calves, with erythematous margins and slightly sunken waxy centres traversed by telangiectatic blood vessels. The spleen is palpable two finger-breadths below the costal margin, but no other abnormality was found.

Investigations.—Hæmoglobin 95%. W.B.C. 3,600, normal differential. E.S.R. 10 mm. in the hour. Plasma proteins normal. Chest X-ray normal.

Histology.—The epidermis shows atrophy. The corium exhibits several sarcoidal nodules. The collagen shows necrobiotic changes. Some smaller vessels show narrowing of their lumina.

Comment.—Since Goldsmith (1935) described the first case of necrobiosis lipoidica unassociated with diabetes mellitus, this type has been reported with increasing frequency. It is clear now that, in this country at least, the condition is commoner in non-diabetics than in diabetics. No definite ætiology, however, has been ascribed to it.

The cutaneous features of the present case are clinically typical of necrobiosis lipoidica and histological examination shows both collagen necrobiosis and sarcoid infiltration. There is both clinical and histological evidence of ocular sarcoidosis and this lesion commenced at the acute onset of the illness five years ago. An over-all diagnosis of sarcoidosis therefore seems reasonable.

My second case showing a similar symptomatology unfortunately did not attend, but a similar case was shown by Drs. O. L. S. Scott and G. A. Beck at a recent meeting of the St. John's Hospital Dermatological Society. In recent years an increasing number of cases of erythema nodosum have been shown to be the result of sarcoidosis and I think that the same thing will happen with non-diabetic necrobiosis lipoidica.

REFERENCE

GOLDSMITH, W. N. (1935) *Proc. R. Soc. Med.*, **28**, 363.

Dr. Henry Haber: This case shows typical sarcoid histology. The collagen exhibits some scleroderma-like changes leading to the clinical appearance of necrobiosis.

Dr. G. A. Beck: The case which I showed at St. John's hospital on June 7, 1956, had lesions apparently typical of necrobiosis; it was only after the histological report suggesting sarcoid was received that we found that she had extensive typical X-ray changes of sarcoid in the lungs. We treated her with cortisone for quite a long time, at least the physicians did, with the idea of reversing the lung signs. There was no change in the lesions on the leg which were more typical even than these. I thought they were clinically indistinguishable from necrobiosis.

Dr. G. A. Hodgson: We do see these cases which look like sarcoid and I wondered if in such persons there might exist some sarcoid state of the skin so that the necrobiosis with vascular changes would then provoke more a sarcoid-like change instead of the ordinary appearance of necrobiosis.

Dr. D. S. Wilkinson: Out of my last 6 or 7 patients who appeared clinically to have necrobiosis, 3 have turned out to have sarcoidosis; 2 had typical involvement of other organs. All 3 had positive Kveim reactions, which were negative in the other cases. I am sure this is no chance association; it is too frequent.

Impetigo Herpetiformis.—M. FEIWEL, M.R.C.P., and D. FERRIMAN, D.M., M.R.C.P.

In September 1951, L. S., a housewife aged 46, was admitted to the North Middlesex Hospital as an emergency in prostration with a confusional state and a diffuse rash. The latter had commenced simultaneously on the inner aspects of the thighs and the front of the chest and had extended rapidly to cover almost the entire body-surface. Her obstetrical history included six normal deliveries and one miscarriage. No rash had ever been observed during gestation or in the puerperium. In her fifth pregnancy (1944) she developed a thyroid swelling, which in 1951 was accompanied by stridor and in June of that year a subtotal thyroidectomy was performed for colloid goitre. Post-operatively, spasmophilia with hypocalcæmia (serum calcium levels of 7·0 mg., and later 6·1 mg./100 ml.) occurred. She was treated with calcium orally as an out-patient and at one of these visits diplopia was recorded.

On admission.—Clusters of pinhead-sized pustules had already coalesced and the confluent areas were partly encrusted. The skin was œdematous and cracks were seen in the creases (Fig. 1). Within a few days delirium and hyperpyrexia (temperature 106° F.) ensued and continuous twitching and jerking movements were observed. These spontaneous movements were probably due to a combination of spasmophilia and profound constitutional disturbance. Chvostek's sign was not demonstrable, but the serum calcium was 5·0 mg. per 100 ml. Her leucocyte-count was 25,000 (92% polys.). She seemed moribund.

Treatment.—Corticotrophin (20 units, six-hourly) and dihydrotachysterol (5 ml. daily) with calcium gluconate (10 grains, i.m., t.d.s.) were promptly prescribed and within forty-eight hours there was a remarkable improvement; indeed she was now alert and the abnormal movements had entirely disappeared. Her temperature was returning to normal. The rash was subsiding and soon resembled exfoliative dermatitis with, however, the characteristic

FIG. 1.—Impetigo herpetiformis, clusters of pustules coalescing to form confluent areas; skin œdematous and cracking.

reddish-brown colour of impetigo herpetiformis. The hair and nails were shed and within a few months healing was complete.

Maintenance therapy consisted of thyroid with both calcium and vitamin D, orally, for her hypothyroid and hypoparathyroid states respectively. Now, five years later, she is in good health and continues to take thyroid (3 grains daily), vitamin D (25,000 units daily) and calcium lactate (10 grains t.d.s.). Impetigo herpetiformis has not recurred.

A brief account of this patient has appeared previously (Ferriman, 1953).

Discussion.—In 1872, Hebra described impetigo herpetiformis as a pustular eruption with serious constitutional symptoms affecting women in pregnancy or in the puerperium. It was later shown that this disease was neither confined to gestation and the puerperium nor to females. Moreover, constitutional disturbance may be absent. Although co-existent hypocalcæmic states are recognized, much of the earlier evidence on this point was purely clinical.

The clinical postulates of Hebra and Kaposi, as modified with time, were listed by Hall (1944), who stated that all attempts to prove an infectious or toxic basis had failed. Beek (1951) reviewed the literature and indicated the incidence of various clinical associations. Of 53 cases, 19 were idiopathic whereas 22 occurred during pregnancy and were accompanied on 12 occasions by hypocalcæmic states either proven or presumed. Another 12 patients had proven or presumed hypocalcæmia and most of these patients had undergone partial thyroidectomy. In view of the increased pituitary activity in pregnancy, it is of interest that one of the idiopathic cases had a pituitary tumour (Trýb, 1921).

The association, as in our patient, with a previous partial thyroidectomy is well documented, the literature revealing good evidence of hypoparathyroidism in 9 cases (Schardorn, 2 cases, 1921; Kyrle, 1926; Brill, 1928, whose case was later reported by Danisch, 1929; Lutz, 1928; Bohnstedt, 1933; Gans, 1933, whose case was re-narrated by both Wendt in 1934 and Schubert in 1936; Bartmann, 1937; Englefeldt and Gentele, 1950). These 9 cases were all women, whose ages ranged from 18 to 50. 2 were pregnant when their dermal lesions appeared. The interval between thyroidectomy and the appearance of the skin lesions varied from three months to twenty-nine years in the 9 patients, 6 of whom died. It is emphasized that 2 of the 3 patients who recovered differed from the rest of the 9 patients in that they alone received adequate treatment by modern standards for their hypocalcæmia. One patient (Gans, Wendt and Schubert) is of unusual interest since it was shown that cessation of this treatment led to relapse of the dermal lesions, which regressed after resuming treatment. A further point of interest concerns one of the patients in the group with pregnancy and hypocalcæmia. It is surmised that this patient had idiopathic hypoparathyroidism since, at her autopsy (Walter, 1922), there was no demonstrable parathyroid tissue.

The clinical picture of our patient exemplifies the severe form of impetigo herpetiformis and although a recent case report by Steppert (1954) includes photographs comparable with ours, his case was less fulminating.

Finally, our clinical impression that corticotrophin was decidedly beneficial must await further communications.

We wish to thank Dr. R. J. Calvert for help in the preparation of these comments.

Section of Surgery

President—ERIC A. CROOK, M.A., M.Ch., F.R.C.S.

[*February* 6, 1957]

The Surgical Significance of the Internal Architecture of the Liver [*Abstract*]

By MICHAEL HOBSLEY, M.A., M.B., B.Chir.

To the surgeon, the liver is an organ that bleeds excessively when cut. To the student of gross anatomy, the liver is preponderantly hepatic veins. These arise from the inferior vena cava near the superior margin of the liver as three main stems, the right, the middle and the left hepatic veins. (Usually the middle springs from, or takes common origin with, the left hepatic vein.) The hepatic veins fan *downwards*, defining three corresponding segments of liver, and the extent of anastomosis between these segments is uncertain though most investigators agree that there is some (Elias and Petty, 1952; Gans, 1955*a*). The left vein drains the classical left lobe, that is the area to the left of the falciform ligament.

The portal veins occupy less than half the volume of the hepatic veins. At the porta hepatis the main trunk of the portal vein divides into a short right and a long left division. Smaller branches fan laterally from these stems, and so tend to run at right angles to neighbouring hepatic veins.

The much smaller bile ducts and hepatic arteries run through the liver substance in close proximity to a portal vein branch, the three structures constituting the "Glissonian system". There are few vascular and no significant biliary anastomoses between contiguous branches, and the areas which these branches define may conveniently be studied by injection of any one of the three components of the system.

Thus post-mortem radiological visualization of the bile ducts shows most commonly the following pattern: *the common bile duct* divides into *right* and *left hepatic ducts;* the former drains the right half of the liver by two main ducts, an *antero-medial* and a *postero-lateral;* while the latter supplies a *branch to the quadrate lobe* and then, crossing the plane of the falciform ligament, divides into an *upper* and a *lower* branch to the left lobe.

The true plane of subdivision of the liver into equal halves is that demarcating the territories of the right and left Glissonian systems. This *principal plane*, first described by Rex (1888) and Cantlie (1898), is well to the right of the plane of the falciform ligament, and can be defined on the surface of the liver by injection of right and left hepatic ducts with different soluble dyes. These diffuse through to the surface in their separate areas. On the anterior aspect of the liver, the plane runs from the gall-bladder notch below to the origin of the central hepatic vein above. Behind, the boundary bisects the gall-bladder fossa and the caudate lobe. This plane is well defined, therefore, by obvious landmarks, and is of corresponding surgical importance. The central hepatic vein also lies in this plane.

All the liver between the principal plane and the plane of the falciform ligament is supplied by branches of the left Glissonian system, given off with rare exceptions to the right of the falciform ligament. Thus the classical *left lobe* has its own separate pedicle from both Glissonian and hepatic vein systems.

In the right half of the liver, the antero-medial and postero-lateral Glissonian branches define corresponding zones, but the boundary between them follows no precise anatomical landmarks, is variable in position, and lacks sharpness near its right extremity. Moreover, the right hepatic vein—contrary to Gans (1955*b*)—is not necessarily a guide to the position of the plane.

To summarize, the liver may be divided into right and left halves about the principal plane, or into right and left lobes by the plane of the falciform ligament. Further subdivision of the right half into antero-medial and postero-lateral zones is less justifiable.

In applying the anatomical findings to surgery, the first and most obvious consideration is that any incision of liver substance should if possible be made with the internal anatomy of the organ closely in mind. For example, a wedge removed from the upper part of the left lobe may interrupt the left hepatic vein in its oblique path downwards and to the left, and so jeopardize the viability of the rest of the left lobe.

As regards the removal of large sections of liver, use should be made of the fact that, there being few blood or biliary vessels crossing the plane of the falciform ligament, and practically none across the principal plane, these planes are relatively bloodless. Therefore we may consider right and left hemi-hepatectomy, and right and left lobectomy.

The further consideration arises that if the Glissonian and hepatic vein pedicles of an area can be secured at the beginning of the operation, a further reduction in the risk of serious hæmorrhage is achieved. *Formal hepatectomies* may be defined as satisfying this requirement. The only operations falling strictly into this category are those of right and left lobectomy, supplied each by a separate Glissonian pedicle, and the right by the right and central hepatic veins, the left by the left hepatic vein. The hemi-hepatectomies are not formal hepatectomies because, while the appropriate Glissonian pedicle can be secured, the central hepatic vein lies in the plane of section and cannot be tied without risk to the remaining half of the central segment of the liver.

Lesser hepatectomies than this have been described. For example, Gans advocates in cases of carcinoma of the gall-bladder a "middle lobectomy", that is the excision of the central hepatic vein segment between falciform ligament and the plane between antero-medial and postero-lateral zones of the right liver half. Patel and Couinaud (1955) mention excision of the lower half of the left lobe. But the indications for an excision of less than the whole of the left lobe must be few. Such operations depend more on the hæmostatic technique of the operator than upon a knowledge of the internal anatomy.

There is one application of left lobectomy deserving special mention. In cases of high obstruction of the common bile duct, Longmire and Sanford (1948) described cutting across the left lobe until a suitably dilated intrahepatic bile duct was found, excising the appropriate wedge of liver and anastomosing the cut end of the bile duct to jejunum. Dogliotti and Fogliati (1954) claimed to have used in 1946 a similar procedure with a left lobectomy as the primary step. This operation is anatomically sounder, and I think it should be commenced by blunt dissection from the region of the inferior end of the liver attachment of the falciform ligament, upwards along the fossa for the ligamentum venosum. In this region, or immediately to the right of the fossa, there runs the bile duct to the quadrate lobe. This duct, even in a normal post-mortem liver, can easily be found and is sometimes quite as large as the main ducts to the left lobe. It is quite possible that where the biliary tree was suffering from the effects of back-pressure this duct might itself be suitable for anastomosis with the jejunum. The operation would be technically simple provided the dangerous relationship of the blunt end of the left portal vein, lying superficial to the duct in the fossa at a distance never less than two inches from the inferior rim of the liver, were remembered. No harm would be done if the duct could not be found or were not large enough, because the dissection could be completed to remove the left lobe and a main duct used as Dogliotti described.

This work was carried out while acting as Research Assistant in the Department of Surgical Studies at the Middlesex Hospital, laboratory facilities having been provided at the Institute of Clinical Research.

The Diagnosis of Acute Pancreatitis

By HENRY WAPSHAW, M.D., Ch.M., F.R.C.S.Ed.

WHEN confronted with a case of acute pancreatitis our responsibility is twofold. Firstly, we have to recognize the condition and secondly, try to identify the type. It is usual to think of two pathological types; the one presents as necrosis and hæmorrhages and the other as œdema or merely swelling or induration of the gland. The custom of referring to the latter as subacute pancreatitis is at times misleading since its clinical differentiation from the destructive form is not always easy in the initial stage. For the purpose of this paper both forms are classed as acute pancreatitis.

The more identifiable features of the disease will be described as they were found in 40 cases—the sum of my experience. There were 26 cases with gross lesions, of whom 12 died, and 14 mild cases with 1 death. The state of the pancreas was ascertained from the following sources: (*a*) autopsy, 7; (*b*) emergency laparotomy, 8; (*c*) delayed laparotomy, 17; (*d*) there remain 3 with large pseudo-cysts who were regarded as necrotic types and 5 with transient symptoms but diagnostic serum or urinary amylase readings who were regarded as benign types. Acute pancreatitis was suspected in only 50% of the series, hence the high operation rate.

Clinical Features

There were 28 females and 12 males and the ages ranged from 40–60 years. 15 patients had experienced *past episodes* of acute abdominal pain. How far these were related to the pancreas is uncertain, but one patient had five relapses and is fit and well to-day.

The *pain* in an established case is intense, gripping and often paroxysmal. It may come on abruptly or take hours to reach its height; it may pass off abruptly or linger as a dull ache; it continued for four weeks in one of the necrotic group. 7 patients were not relieved by morphine. Objective studies of pain are not altogether reliable, but one gained the impression that some of the benign group suffered as much as those with severe lesions, though for a shorter period as a rule. Then again some of the latter appeared to be so overcome that they could scarcely muster the effort to communicate their feelings. Possibly for this reason, two fulminating cases did not actually complain of any pain. They were exceptional in that they developed pancreatitis and died two and four days after operations on the stomach.

The pain commenced in the following parts: supra-umbilical area, 27 cases; right sub-costal, 4; left sub-costal, 4; left loin, 2; and thoraco-lumbar, 1. The pain passed through to the back in 50% of the series.

Sickness with vomiting occurred in 33 patients. Among those unaffected were the two post-operative cases mentioned. It was not so pronounced or lasting, though just as prevalent, in the benign group when compared with the grossly affected (*see* Table I). The main characteristic of the sickness seems to be its persistence even after the pain has gone.

Table I.—Summary of Clinical Findings

	Total series (40 cases)	Hæmorrhagic necrosis (26 cases)	Œdema or induration (14 cases)
Pain	38	24	14
Sickness ..	33	22	11
Cyanosis ..	9	5	4
Jaundice ..	12	6	6
Palpable mass..	10	10	—
Glycosuria ..	7	6	One known diabetic

Passing to the more *objective* features, the behaviour in bed varied widely from patient to patient. Some were restless, others lay with their knees drawn up, while others were apathetic, heavy-eyed, and seemingly oblivious to their surroundings. There was little distinctive about the temperature chart. Half of the patients were in a state of prostration during the first day or two but a gross fall in blood pressure was noted in a minority. Hypotension as a sign of pancreatitis is, I believe, over-stressed and its absence should not exclude the disease.

Cyanosis either confined to the lips or more widely distributed occurred early, and was present in 9 patients of whom 1 died. Its meaning was difficult to assess, but I surmise that these patients were unable to breathe properly owing to the pain. Discoloration of a more lasting nature at the umbilicus or loin, the signs of Cullen and Grey Turner, was absent throughout this series. A tinge of *jaundice* was observed in 10 patients and bile detected in the urine in 2 more. I explored the biliary tract in 8 of these at a quiescent period and in none were stones or other cause found. A likely explanation is compression of the bile duct as it ran behind the diseased pancreas (*see* Table I).

The areas of *maximum tenderness* were sited in the following places: supra-umbilical area, 16 cases; right sub-costal, 13; left sub-costal, 4, and left loin, 2. Muscular rigidity and distension were too vague for an accurate statement of their incidence.

A *mass* was felt in the upper abdomen in 10 patients. During the earlier stages this seems to be of the nature of a tangle of œdematous omentum and loops of bowel and later on due to a localized collection of fluid or pus. This sign was confined to the severe form (*see* Table I).

Albuminuria was a constant finding. *Glycosuria* was present in 7 cases, 2 of whom were known diabetics.

Table I lists the collective findings and shows how they were distributed in the two groups. Generally speaking, pain, sickness, cyanosis and jaundice were as prominent in the one group as in the other. Bearing in mind that almost half of the patients with necrosis died, the distinguishing features among the survivors were the longer spells of pain and sickness, the presence of a palpable mass, and glycosuria.

Diagnostic Methods

There are now several methods of detecting the characteristic enzyme response of acute pancreatitis but procedures do not concern us here. However, it is essential for diagnosis that samples of urine or blood for the amylase estimation should be taken within two days of the onset of symptoms.

The serum *amylase findings* in 14 of the series are presented in graphic form (*see* Fig. 1). Somogyi's method was used. They were serial observations and show how rapidly the elevated values return to normal levels. This rise in the amylase content of the blood or urine is not to be regarded as an index of the severity of the pancreatic lesion. What then does it indicate? The following experiment, which was designed to find out the effects of morphine on the serum amylase content, may help in elucidating the mechanism. As is well known, morphine stimulates the muscular tissue around the lower end of the bile duct to contract, thereby interrupting the flow of bile for periods of an hour or even longer. Fig. 2

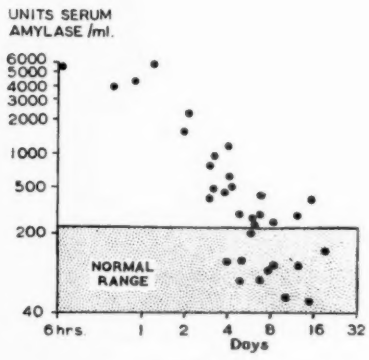

Fig. 1.

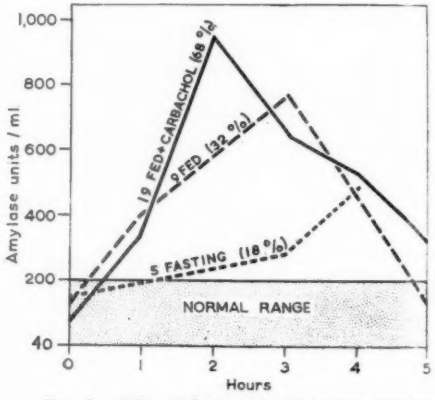

Fig. 2.—Effects of morphine on serum amylase in 84 normal persons.

furnishes evidence from the amylase content of the serum that the flow of the pancreatic secretion is likewise affected on occasion. 84 volunteers under experiment were divided into three groups of 28. Prior to receiving morphine the first fasted; the second received an ordinary three-course meal and the third had a similar meal plus carbachol (B.P.) intramuscularly (Wapshaw, 1953). The averages of those with raised readings in each of the three groups are presented. The numbers affected and the height of the response seemed to be proportional to the secretory activity of the gland and doubtless the duration of the obstruction resulting from the drug-induced spasm. I do not infer that an obstructive factor is the main case of acute pancreatitis but rather that the major ducts of the gland become secondarily occluded as a result of the distortion of its parenchyma. The above findings also indicate that the pancreas can be functionally deranged short of producing the clinical picture of acute pancreatitis, and thereby impugn to some extent the specificity of the amylase test as a diagnostic procedure.

However, the amylase findings are in most cases of pancreatitis dependable during the first twenty-four hours. By the end of the second or the third day they are apt to cause some doubts, especially when the question of a "missed" perforated peptic ulcer arises. Such cases, as is known, sometimes do have raised amylase readings, when the ferment lying free in the abdomen is particularly potent. Evidence of a continuous drop in the serum or urinary levels unassociated with air under the diaphragm helps to substantiate the correct diagnosis. There is little to choose between the urine or the serum as test fluids in performing the test. However, advanced renal disease may lead to inconsistencies, as illustrated by the case referred to in Table II. Note that the serum amylase values were raised well after the condition had settled, yet the urinary index was low. The persistently raised readings obtained in subsequent months confirmed the suspicion that here was an instance of faulty excretion of amylase from the blood as a result of renal failure.

There remain the *serum calcium* levels as an indication of the type of pancreatitis. In the hæmorrhagic form the presence of widespread fat necrosis imposes an excessive demand on the available calcium. For this reason there is in some cases a reduction in the serum calcium, which occurs around the third day and lasts a few days more.

TABLE II.—ACUTE PANCREATITIS: CHRONIC NEPHRITIS

H. C., female, 44 years

Duration of illness	Serum amylase Somogyi units/ml.	Urinary amylase Wohlgemuth units
10th day	1,180	
12th ,,	640	5
15th ,,	530	10
25th ,,	800	
	(Blood urea 166 mg.%)	
2nd month	800	
3rd ,,	400	
5th ,,	450	
7th ,,	200	

(Died two years later in uræmic coma, blood urea 213 mg.% after second attack of acute benign pancreatitis.)

SUMMARY

The pain and sickness are the most prominent symptoms. The relative inconspicuousness of the signs is itself suggestive of the disease. The points in favour of the destructive form as against the benign form are the prolongation of the symptoms, a palpable mass, glycosuria, and a drop in serum calcium. It cannot be over-emphasized that a high rise in the amylase content of the blood or urine during the first two days of illness is an invaluable diagnostic sign. Equivocal findings thereafter may still be shown to be appreciably raised by carrying out further tests.

Unexpected Post-operative Bleeding Due to Hæmorrhagic Disease

By OWEN DANIEL, M.B., B.S., F.R.C.S., H. T. SWAN, M.B., Ch.B., M.R.C.P., and E. K. BLACKBURN, M.D., F.R.F.P.S.

The University Department of Surgery and the Department of Hæmatology, The Royal Infirmary, Sheffield

THE hæmorrhagic diseases in which trauma is likely to be followed by abnormal bleeding are usually easily recognized after simple clinical examination. Surgery is then undertaken only if absolutely essential and only after every possible step has been taken to minimize the expected blood loss (Macpherson and Learmonth, 1956).

The usual warning of the presence of a hæmorrhagic state is the development of episodes of excessive bleeding or bruising after minor injury, or of spontaneous hæmorrhage from the intestinal, genito-urinary or respiratory tract. Reports of similar conditions in blood relatives should also be taken seriously, and the presence of petechiæ, unexplained bruising, jaundice, a biliary fistula, splenomegaly, chronic anæmia or chronic diarrhœa must of course never be disregarded.

Occasionally surgery has to be performed on a patient suffering from a severe hæmorrhagic disorder which has produced no recognizable symptoms or signs before operation. We have recently met this complication after gastrectomy in a patient with chronic myeloid leukæmia (Blackburn and Daniel, 1957) and after open perineal biopsy for carcinoma of the prostate (Swan *et al.*, 1957). This experience has led us to review very briefly those conditions which may cause unexpected bleeding after operation.

Primary vascular abnormalities which lead to a hæmorrhagic state commonly present with purpura or bruising and as such are easily recognized, although sometimes these conditions come to light only during surgical operation. It is also possible for allergic purpura of the type usually associated with Henoch's name to present with abdominal pain, vomiting or intestinal bleeding and under these circumstances operation may be performed before other characteristic signs such as cutaneous and mucosal hæmorrhages appear (Wintrobe, 1956).

Hæmophilia and allied disorders are usually recognized before surgery is undertaken. Difficulty may, however, arise where there is no clear history of abnormal hæmorrhages since early childhood or relevant family history. This difficulty occurs most often in mild forms of hæmophilia or Christmas disease and these mild forms constitute an appreciable proportion of the total number of patients suffering from these diseases. In such cases a deep hæmorrhage may easily be mistaken for a suppurative condition and surgical drainage attempted with disastrous results.

During the last few years increasing attention has been given to the biological significance of fibrinolysis and acquired fibrinogen depletion. In the normal organism there appears to exist an equilibrium between the fibrin-producing process of blood coagulation and the fibrin-destroying properties of certain enzymes. Fibrinolytic enzymes and thromboplastins have been found in the blood and the tissues, especially the prostate, lungs and pregnant uterus. The release of abnormal quantities of these tissue enzymes has been reported as causing dangerous bleeding after operations on the prostate, extensive operations on or injuries to the lungs, premature separation of the placenta, amniotic embolism, and certain other obstetric complications (Astrup, 1956).

Increased fibrinolysis has been demonstrated in shocked states, in anxiety, after heavy muscular work, after the injection of adrenaline, and in certain immune reactions (Macfarlane and Biggs, 1946). The shock of severe surgical operation may thus induce a hæmorrhagic state. It has also been found that the administration of large quantities of stored blood in a relatively short period of time may lead to a platelet deficiency sufficient to interfere with blood coagulation (Krevans and Jackson, 1955). Here then are the possibilities of a dangerous vicious circle.

Carcinoma of the prostate can lead to a hæmorrhagic diathesis in many ways, such as through extensive invasion of the bone-marrow as well as through the production of circulating proteolytic enzymes (Prout *et al.*, 1956).

Abnormal proteolytic activity has also been reported in the plasma of two men undergoing prostatectomy for benign disease—both suffered severe post-operative bleeding and death resulted in one (Scott *et al.*, 1954).

It is clear that no surgical procedure should be performed on a patient with carcinoma of the prostate if there is evidence or even suspicion of a hæmorrhagic diathesis. As a first step œstrogens should be administered. If the cancer is sensitive to œstrogens the bleeding tendency will thereby be controlled.

If abnormal bleeding is encountered unexpectedly during the course of a surgical operation, the following procedures should be undertaken:

(1) Careful surgical hæmostasis.

(2) Restoration of blood volume by transfusion.

(3) Immediate laboratory investigations to determine the specific hæmatological defect or defects so that appropriate therapy can be started as soon as possible.

(4) If a fibrinogen deficiency can be demonstrated, fibrinogen should be given by intravenous injection. It should be noted that whole blood is almost valueless in the specific treatment of hypofibrinogenæmia, but if pure fibrinogen is not available concentrated plasma should be used instead.

(5) If the bleeding is associated with carcinoma of the prostate attempts should be made to suppress the tumour by œstrogens. Benefit has also been reported from the administration of cortisone and corticotrophin in patients in whom all other methods of treatment were of no avail (Stefanini *et al.*, 1953).

ACKNOWLEDGMENTS

We are grateful to the Board of Governors of the United Sheffield Hospitals for a grant through the Hæmatology Research Fund and for support from the Yorkshire Council of the British Empire Cancer Campaign.

Pneumonectomy for Agenetic Lung.—M. C. WATERFALL, F.R.C.S.

In September 1954 a 45-year-old German woman, who had lived in England for twelve years, was admitted to Kingston Hospital with ten years' progressive breathlessness, cough with 3 oz. of purulent sputum daily, tiredness and headaches. When she had "pneumonia" at the age of 10 her doctor noticed her heart was "on the right side". During childhood she frequently had a productive cough.

On examination.—She was plump with second degree clubbing. The trachea was deviated to the right. There was flattening of the right side of the chest and the apex beat was palpable in the 5th right intercostal space. Heart sounds normal. The breath sounds were normal over the upper part of the right chest anteriorly and all over the left side. Posteriorly to the right of the spine there was loud bronchial breathing. Scattered rhonchi on both sides. She was producing 3 to 4 oz. of thick, green sputum daily.

Investigations.—Chest X-ray: Heart on the right, dense triangular opacity in the position of a collapsed middle and lower lobe.

Bronchoscopy: The carina was rotated clockwise. Thick pus welled up from the right lower lobe. A bronchogram confirmed there was distortion of the mediastinum and showed that the right lower lobe bronchus ended blindly (Fig. 1).

FIG. 1.—Bronchogram showing heart pulled over to the right and blind ending of right bronchial tree. Aerated lung in the right chest is part of left upper lobe.

Treatment.—November 1954 right pneumonectomy.

The left upper lobe had herniated across the mediastinum and filled the space normally occupied by the right upper lobe. The right lung was very small, solid and densely adherent to the diaphragm and chest wall. The pulmonary artery and veins were slightly smaller than usual and bronchial arteries large. The lung was removed and the bronchus closed with wire.

Convalescence was uneventful.

She is now very well, her exercise tolerance is much improved and she has no sputum.

This case illustrates the well-known fact that removal of non-aerating lung increases the exercise tolerance, as the airless tissue acts as a shunt. This woman was thought to have agenesis of the lung rather than an acquired condition as the calibre of the right main bronchus was normal.

Waldenström's Syndrome or Macroglobulinæmia.—D. W. Oxbrow, M.B., B.S. for S. Karani, M.B., B.S., M.R.C.P.).

Mr. B., aged 51, was admitted to hospital on 6.9.56 complaining of gradual impairment of sight for two to three years, which had become much worse in the previous two months. He also complained of three years' recurrent epistaxes which required hospital treatment, and severe bleeding from hæmorrhoids which had ceased after hæmorrhoidectomy twelve months previously. He had noticed gradually increasing weakness and shortness of breath on exertion for four to six months.

On examination.—He appeared to be moderately anæmic clinically, pulse 88, regular; blood pressure 145/105.

There was generalized glandular enlargement, but no enlargement of the liver or spleen. Examination of the fundi showed marked venous dilatation with numerous hæmorrhages. There was no exudate or papillœdema (Fig. 1).

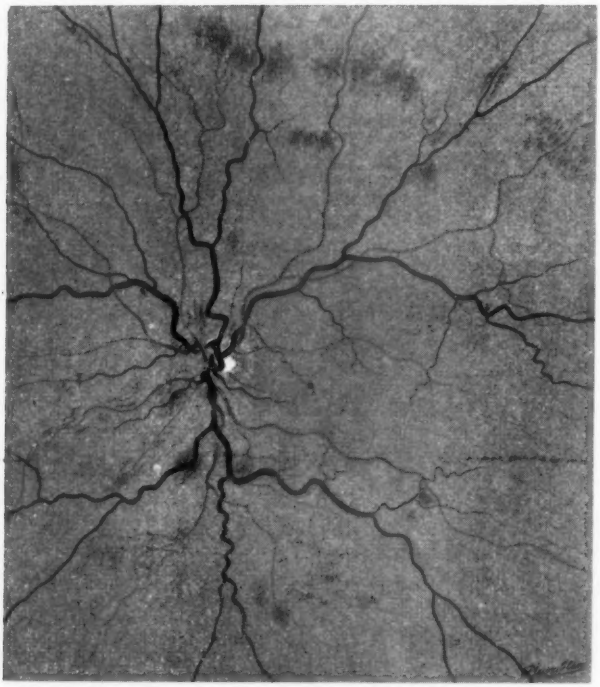

Fig. 1.—Fundi appearances showing venous dilatation and hæmorrhages.

Investigations.—Hb 23%. W.B.C. 5,000, varying from 4,000 to 7,000. Lymphocytes initially 40% rising to 50%. Platelets 43,000 initially, rising to 120,000. Occasional nucleated red cells and metamyelocytes.

23.1.57: Reticulocytes 3·7%. E.S.R. was barely recordable at 1 mm. in the first hour.

Serum proteins: Total 11·1, albumin 4·7, globulin 6·4 grams/100 ml., A/G ratio 0·73 : 1. The serum proteins rose to 13 grams/100 ml. of which 10 grams were globulin.

Electrophoresis showed the abnormal globulins to be entirely in the γ-globulin fraction.

Ultracentrifugation (Dr. A. S. McFarlane) showed that there were at least two macroglobulins of high molecular weight present in the serum.

Serum fibrinogen 120 mg./100 c.c.

Tests depending on abnormal globulins were as follows: Thymol turbidity 25 units. Thymol flocculation 5+ units. Colloidal gold 5+ units. Formol gel positive. Bleeding time: three minutes. Clotting time: eight and a half minutes. Examination for LE cells negative. Coombs test negative. Sternal marrow: Poorly cellular sample. 80–90% mature lymphocytes. Lymph gland biopsy: Proliferation of lymphocytes;

prominent sinuses filled with reticulum and inflammatory cells, with fibrosis of the hilum of the gland. Chest X-ray: Cardiac enlargement. Prominent vascular markings. X-ray of skeleton normal.

The patient developed a large right pulmonary infarct on the fifth day after admission to hospital, and subsequently a right pleural effusion, but since then he has slowly responded to repeated transfusions and prednisolone, with disappearance of retinal hæmorrhages and improvement of vision from 6/60 right 6/60 left, to 6/9 right and 6/24 left. He still has occasional mild epistaxes.

Discussion.—Jan Waldenström (1944) was the first to recognize this condition when he described two cases of essential hyperglobulinæmia with fibrinogenopenia. Ferriman and Anderson (1956) reported a case with identical signs and symptoms to those of Waldenström's original case and collected 16 other cases from the literature. They emphasized the characteristic features which may be observed in the fundi, namely venous dilatation with scattered hæmorrhages but without exudate or papillœdema.

The two diseases which may come into the differential diagnosis are multiple myeloma and chronic lymphatic leukæmia. In the former there is evidence of characteristic bone-marrow changes, a history of bone symptoms and characteristic X-ray appearances of the bones; in the latter the appearances of the bone-marrow, gland biopsy and the progress of the disease usually establish the diagnosis.

Some interesting features of this illness need further work to explain them. The excess of abnormal globulin appears to be related to the proliferation of lymphocytes and their metabolic breakdown. The bleeding may be explained by the lack of fibrinogen and platelets, and perhaps also by venous distension caused by unduly viscous blood. The anæmia may be the result of (*a*) blood loss, (*b*) interference with marrow function by lymphocytic replacement, (*c*) multiple thrombi resulting from the peripheral stasis caused by increased viscosity of the blood. These thrombi may account for the low platelet and fibrinogen figures and perhaps for the poor response to transfusions, e.g. 8 pints of blood given in ten days raised the patient's hæmoglobin by only 22% and 4 pints in five days by only 14%.

Treatment.—There is no satisfactory treatment. Blood transfusions produce only slight improvement in the blood picture and though cortisone may be used (as in this case) for its theoretical action in depressing lymphoid tissue there has been no good effect here either clinically or on the serum protein figures.

Renal Failure Treated with Prednisolone.—J. E. LENNARD-JONES, M.B., M.R.C.P. (for RICHARD ASHER, M.D., F.R.C.P.).

History.—A boy, aged 16, was admitted to hospital on 23.12.56 complaining of swelling of his face, abdomen and legs. Three weeks previously a superficial skin graze became infected. A week later he began to feel unwell and ten days later puffiness was noted around his eyes. Subsequently his ankles, legs and abdomen became swollen. The patient himself had noted a gain of over 12 kg. in weight over the ten days before admission. There was no history of recent sore throat, of red urine or of renal pain. A routine urine test was normal two months previously.

Clinical findings.—Gross œdema of the face, body and legs. Pleural effusions. Ascites. Blood pressure 160/110. Throat normal. Healed abdominal skin graze.

Initial investigations.—Urine—gross albuminuria but no red blood cells or casts. Total serum protein—3·6 grams/100 ml. (Albumin 2·5 grams/100 ml.) Electrophoresis of serum proteins—α_2 and β-globulin raised, γ-globulin low. Protein content of œdema fluid—0·1 gram/100 ml. Blood urea—46 mg./100 ml. Serum cholesterol—512 mg./100 ml. Throat swab—scanty β-hæmolytic streptococci.

Course in hospital (*see* Fig. 1).—The acute onset of the illness, its possible relationship to streptococcal infection and the finding of hypertension suggested immediately a diagnosis of acute glomerulo-nephritis (Ellis Type I). However, the findings on investigation clearly pointed to a diagnosis of nephrosis.

In the hope that a spontaneous diuresis might occur the only measures adopted during the first three weeks after admission were fluid restriction, a largely carbohydrate diet and course of parenteral penicillin. During this time considerable anxiety was felt because increasing œdema caused breathlessness; hypertension and gross proteinuria persisted and the blood urea rose (highest 123 mg./100 ml.). The treatments available were limited

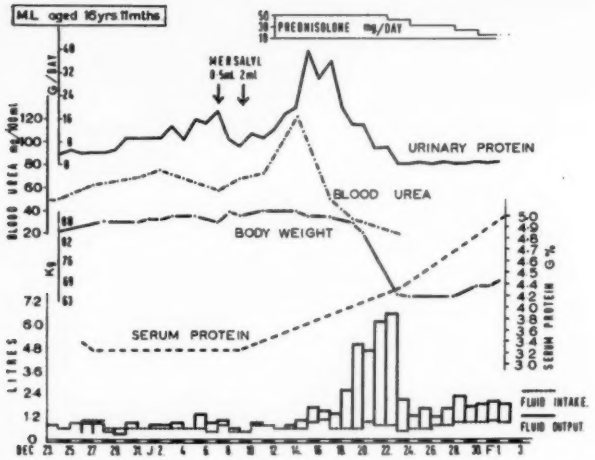

FIG. 1.—Showing the diuresis which occurred after treatment with prednisolone. The diuresis began before a fall in the urinary protein loss.

as mercurial diuretics were not effective, cation exchange resins appeared contra-indicated owing to the renal failure and the boy was too ill for malarial therapy. It was decided that prednisolone should be given and that acupuncture should be performed if this failed.

Three days after starting prednisolone a diuresis began which reached a climax between the seventh and the eleventh days when 23·4 litres (41 pints) of fluid were passed and the body weight fell 22 kg. The hypertension disappeared, the proteinuria lessened and the blood chemistry returned to normal. Prednisolone was gradually discontinued without increase of albuminuria or return of œdema.

Comment.—This case again demonstrates that a diuresis can occur before a fall in the urinary protein (Roscoe, 1956). The successful result of treatment with prednisolone despite gross œdema and a raised blood urea seems noteworthy. It is proposed that this boy should be maintained on small doses of prednisolone if gross proteinuria or œdema recur.

(We wish to thank Dr. D. J. Crockett for estimating the protein content of the œdema fluid.)

DISCUSSION ON RECURRENT OTITIS MEDIA IN CHILDREN

Mr. Lionel Taylor: Otitis media in children is a complication of upper respiratory infection. The onset is usually abrupt with pain and raised temperature, but otitis media may arise insidiously. In the untreated and uncomplicated child the drum will rupture by pressure necrosis within hours and the pain at once be relieved, or a minor infection settle without rupture. When antibiotics are exhibited for a full five days the intratympanic effusion will slowly subside as the infection is combated and the fluid drain away through the eustachian tube or be reabsorbed in the ear and mastoid cell system. A certain amount of residuum will remain, forming fibrosis, and therefore hearing will not return to "normal" for three to four weeks or longer. There may be some permanent impairment in hearing especially if attacks are repeated. If a myringotomy is done under general anæsthetic before the drum ruptures, pain will be at once relieved and the linear incision will heal far more quickly than the circular hiatus left by necrosis; the contained fluids will escape completely and hearing will return to normal very quickly. Resolution will be hastened by use of antibiotics in adequate dosage after myringotomy, supported by decongestive nasal drops and aural toilet. Causes of recurrent otitis media may be listed as shown in Table I.

TABLE I.—CAUSES OF RECURRENT OTITIS MEDIA IN CHILDREN

1. Eruption of teeth.
2. Enlarged adenoids.
3. Persistent perforation of tympanic membrane.
4. Latent mastoid infection.
5. Lymphoid hyperplasia.
6. Idiopathic.

Teeth.—The relationship between teething and otitis media is undisputed but the mechanics of this are not proven. Presumably there is reflex congestion of the middle ear which allows pooling of mucus in the tympanum. This may become infected from the blood stream if the child catches a cold. Treatment of the otitis media is as outlined earlier.

Adenoids.—Where there are large adenoids these, when infected, will swell up and obstruct the pharyngeal end of the eustachian tube. Stagnation of mucus occurs with subsequent infection either directly from the nasopharynx or by the blood stream, resulting in otitis media. When the otitis media recurs with every severe cold, removal of adenoids is indicated. Between attacks these children will have intact tympanic membranes but these are usually indrawn. They also have symptoms of enlarged adenoids such as mouth breathing and snoring. In a well-judged case no further otitis media occurs with subsequent colds. It is often convenient to remove the tonsils at the same operation where there has been any history of tonsillitis, although the tonsils have no direct bearing on the otitis media. These children often have an associated maxillary antritis which clears up after removal of adenoids unless there is an additional vasomotor rhinitis.

Perforation.—The majority of ruptured tympanic membranes heal, but a few remain with a perforation. This does not necessarily affect the hearing, but such a perforation remains a potential source of danger. If, for instance, water gets into the external meatus from under-water swimming or vigorous hair washing, it may enter the middle ear. If it does so, otitis media will follow. Similar effects will be produced by syringing such an ear for removal of wax. Until recently there was no satisfactory treatment for this condition, but now the operation of myringoplasty will prove of value for some of these cases.

Latent infection.—Where inadequate dosage of antibiotics is used, particularly where the drum has not ruptured, latent infection may persist. After a time of apparent normality the otitis media will flare up again within two to four weeks, or may present as mastoiditis, or one of its complications. One such boy of 7 complained two weeks after treatment of seeing two television screens. He was admitted to hospital and found to have papilloedema. The only aural sign was reddening of the deep meatus in the attic region and some deafness, but at operation the mastoid cell system was full of cheesy granulations and he had a sterile lateral sinus thrombosis. His hearing returned to within normal limits two months later. A second child presented with vomiting and other signs of meningism. His aural sepsis was minimal, but the cell system was completely disorganized. Lumbar puncture in each child showed the pressure to be raised but culture was sterile confirming a diagnosis of otitic hydrocephalus. Again after a simple Schwartz mastoidectomy, recovery was complete and uncomplicated and hearing became normal.

Hyperplasia.—Removal of adenoids, especially in the very young, may be followed by diffuse lymphoid hyperplasia of the nasopharynx. The pharyngeal end of the eustachian tube contains lymphoid tissue. Usually this causes little trouble but in these children hypertrophy may be responsible for recurrent obstruction with resultant otitis media. This cannot be removed successfully by surgery, but responds on occasion to radiotherapy.

Idiopathic group.—Finally there remains a group of children in whom otitis media recurs with monotonous regularity despite every treatment. These patients, whose otitis media must be labelled idiopathic, remain one of the unsolved otological problems. Such children have clear nasal airways between attacks, with no symptoms of enlarged adenoids or sinusitis. Ear drums are of normal lustre and are not indrawn. Between attacks Rinne's test is positive and Weber's central. Possibly the eustachian tubes are more widely open than normal, allowing muco-pus to gravitate up the tube in sleep against the ciliary stream, or very rarely it is possible that such children have had their adenoids removed and at that time the eustachian cushions were damaged by the curette.

Both the lymphoid hyperplasia group and the idiopathic group will start a steady improvement about the age of 14. If masterly inactivity has been possible up to that time the reward will now be gained in that the attacks will cease as the lymphoid tissues regress and assume adult form.

Dr. I. Friedmann: The role of the clinical pathologist in the management of otitis media depends, to a certain extent, on the general practitioner and surgeon. The surgeon may feel less inclined to ask the clinical pathologist too many questions. The general practitioner has also adopted a more active attitude when using the antibiotics as it can be unwise to delay treatment until the results of the laboratory tests are to hand.

The value of the sensitivity test cannot be doubted but its results are not immediately available. This is due to the practical difficulties and to the considerable amount of work involved. In addition, it has become increasingly difficult to keep abreast of developments in this field. Several new antibiotics have been introduced recently and our personal laboratory experience of them has so far been limited.

Besides a critical attitude of mind the interpretation of such information presupposes a knowledge of the bacteriology and pathology of a given disease. The fact is sometimes overlooked that treatment with antibiotics does not represent treatment of a disease, as does surgical treatment, but is directed against the causative organisms. It is not entirely correct to talk of the antibiotic treatment of otitis media. It would be more accurate to refer to the treatment of e.g. staphylococcal, pneumococcal, &c., infections of the middle ear.

The best assistance the clinical pathologist can give is based on the long-term study of the bacteriology, histopathology and experimental pathology of otitis media.

TABLE I.—BACTERIOLOGY OF ACUTE OTITIS MEDIA IN 2,441 PATIENTS
(Overall incidence of micro-organisms in 1952–56)

	Number of strains: 3,391	%
Staphylococcus pyogenes	1,022	(41·8)
Staphylococcus pyogenes penicillin resistant	411	(16·8)
Streptococcus pyogenes	669	(27·4)
Streptococcus viridans	157	(10·6)
Streptococcus pneumoniæ	103	
E. coli	103	(4·2)
B. proteus	157	(6·4)
Ps. pyocyanea	136	(5·5)
Mixed	285	(11·7)
No growth	348	(14·2)

The overall incidence of the predominant organisms has not varied greatly in the years

1951 to 1956 (Table I). Gram-positive cocci have predominated and have on the whole remained sensitive to penicillin. There were no penicillin-resistant strains among the 669 strains of *Streptococcus pyogenes*, isolated from 27·4% of all patients.

The overall incidence of *Streptococcus pneumoniæ* and *viridans* has remained low (Friedmann, 1952). Type 3 pneumococci, though frequently encountered, appeared to have no untoward effect on the course of acute otitis media. In 1956 about 30% of our pneumococci belonged to type 3.

The overall incidence of *penicillin-resistant* strains of *Staphylococcus pyogenes* was 16·8%. 4·18% of all staphylococci showed *in vitro* resistance to ten units of penicillin. These figures have remained remarkable steady in our hospital.

Contrary to the experience in other fields there has emerged no clinical or pathological evidence which might incriminate the penicillin-resistant *Staphylococcus pyogenes*. There has been no evidence of a change in the clinical picture of acute otitis media and the number of otogenic intracerebral complications has remained negligible. Moreover, clinical experience shows that patients with acute otitis media harbouring penicillin-resistant staphylococci may respond favourably to penicillin treatment.

In the writer's opinion penicillin has remained the antibiotic of choice in the treatment of acute otitis media.

TABLE II.—BACTERIOLOGY OF RECURRENT OTITIS MEDIA IN 917 PATIENTS
(Overall incidence of micro organisms, 1952–56)

	Number of strains, 1,030	%
Staphylococcus pyogenes	267	(29·1)
Staphylococcus pyogenes penicillin resistant	162	(17·6)
Streptococcus pyogenes	195	(21·2)
Streptococcus viridans	53	(11·1)
Streptococcus pneumoniæ	49	
E. coli	51	(5·6)
B. proteus	80	(8·7)
Ps. pyocyanea	67	(7·3)
Mixed	93	(10·1)
No growth	13	(1·4)

The present writer has defined a recurrence of otitis media as the recurrence of an acute infection after a symptom-free interval of an arbitrary period of six months. As the figures indicate, the overall bacteriology is similar to that found in acute otitis media (Table II). It is interesting to note that the number of negative cultures was lowest in this group.

TABLE III.—BACTERIOLOGY OF CHRONIC OTITIS MEDIA IN 1,700 PATIENTS
(Overall incidence of micro organisms, 1952–56)

	Number of strains: 2,067	%
Staphylococcus pyogenes	539	(31·7)
Staphylococcus pyogenes penicillin resistant	219	(12·9)
Streptococcus pyogenes	119	(7·0)
Streptococcus viridans	57	(4·6)
Streptococcus pneumoniæ	21	
E. coli	138	(8·1)
B. proteus	432	(25·4)
Ps. pyocyanea	218	(12·8)
Mixed	143	(8·4)
No growth	181	(10·6)

The shift towards a predominance of Gram-negative bacilli is characteristic of the bacteriology of chronic otitis media. There are several efficient antibiotics against the majority of the Gram-negative organisms. The majority of organisms of *E. coli* type, *A. aerogenes* and *Klebsiella pneumoniæ* (Friedlander's bacillus) have shown *in vitro* sensitivity to streptomycin, chloramphenicol and tetracycline. *Ps. pyocyanea* was usually sensitive to polymyxin B; *B. proteus* was sensitive to streptomycin and chloramphenicol.

The management of chronic otitis media is largely surgical owing to the irreversible changes of bone and mucosa.

The histopathology of otitis media.—One of the objects of the present investigation was to try and solve the question as to whether the pathology of otitis media or mastoiditis has changed since the advent of the antibiotics, a change often suggested. For this purpose bone chips removed at recent mastoidectomy operations have been dissected and examined, and the pathology of experimentally induced otitis media in the

guinea-pig studied. It has been pointed out in previous reports (Friedmann, 1955*a* and *b*; 1956) that there was no microscopical evidence to suggest a fundamental change in the pathology of otitis media.

[Slides illustrating the irreversible bone and mucosal changes, with particular reference to the significance of epidermoid cholesteatoma and cholesterol granuloma were shown.]

Antibiotic treatment of experimental otitis.—The injection of various organisms, such as *Ps. pyocyanea*, *Streptococcus pneumoniæ* and *B. proteus*, into the middle-ear cavities of the guinea-pig produces otitis media (Friedmann, 1955*a* and *b*).

The experiment to be described was carried out with a strain of *Streptococcus pneumoniæ* (Type 3) isolated from a case of acute otitis media. This strain spread regularly from the infected to the non-infected ear of the animal causing bilateral chronic otitis media. Guinea-pigs were divided into four groups. After the intra-aural injection of a suspension of the organism, Group 1 was kept as untreated controls; Group 2 was treated immediately with terramycin for intramuscular injections, giving 50,000 units daily for six days. Group 3 was treated in the same way but only after seven days following infection and Group 4 a fortnight after infection.

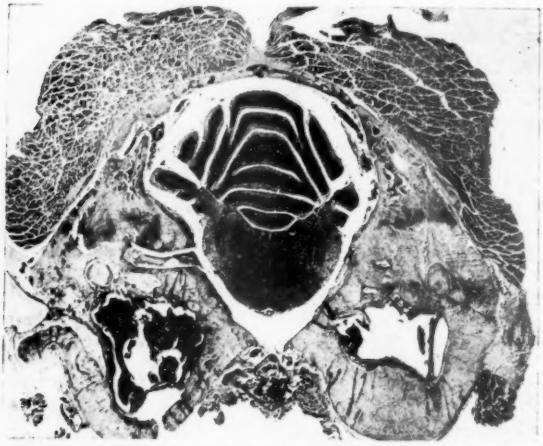

FIG. 1.—Non-treated control animal showing bilateral chronic otitis media sacrificed six months after right intra-aural infection with *Streptococcus pneumoniæ*. ×3. H. and E. G.P. 389.

Result.—All animals survived and were killed six months after infection. The control animals in Group 1 developed bilateral chronic otitis media leading to a great deal of suppuration and bone formation in both ears (Fig. 1). In Group 2 the infection remained localized in the infected ear causing only some thickening of the bulla and slight suppuration (Fig. 2). *In Group 3 the infection appeared to be completely cured.* There was no evidence of infection in either ear (Fig. 3). In Group 4 the infection, although prevented from spreading to the non-infected ear, caused chronic otitis media in the infected ear (Fig. 4).

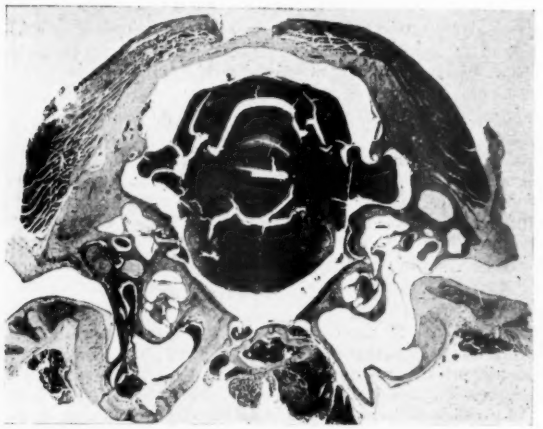

FIG. 2.—Animal treated with terramycin immediately after right intra-aural infection with *Streptococcus pneumoniæ* and sacrificed after six months. Moderate otitis media in infected ear; non-infected ear healthy. ×3. H. and E. G.P. 391.

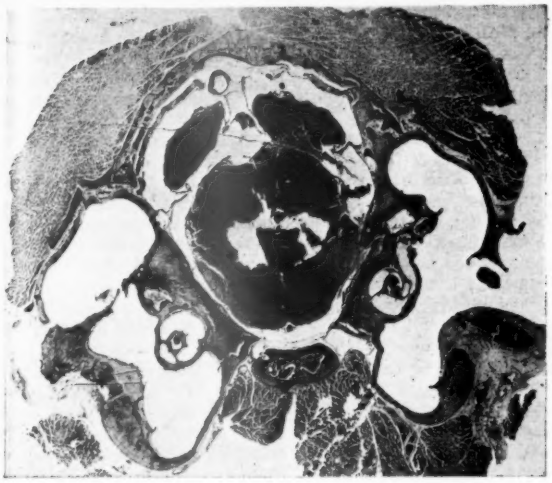

FIG. 3.—Treatment delayed until seven days after infection. Animal sacrificed after six months. There is *no evidence of otitis media* in the infected (or non-infected) ear. ×3. H. and E. G.P. 397.

FIG. 4.—Treatment delayed until fourteen days after infection. Animal sacrificed after six months. The infected ear shows fully developed chronic otitis media but the infection was prevented from spreading to the non-infected ear. ×3. H. and E. G.P. 401.

I cannot offer an entirely satisfactory explanation of these results; but the experimental evidence appears to confirm the clinical experience that there is a time for antibiotic treatment of otitis media, as there is a time for surgery.

Dr. G. F. Abercrombie: Between 1924 and 1934 I attended 82 patients who had between them 115 attacks of otitis, of which 35 were bilateral, giving 150 drumheads for observation. Of these, 80 resolved without complication: in 25, the drumhead perforated with 19 recoveries, 3 secondary myringotomies and 3 mastoid operations; in 45, primary myringotomy was done with 37 recoveries and 8 subsequent mastoid operations. At the end of this series, no case of acute otitis media had been allowed to become chronic and no patient was left with a

running ear. Of the 82 patients, 10 came to a mastoid operation, and 12%, or something near it, was the common finding of those days.

Then, as now, in two attacks out of three, an antecedent infection in the nasopharynx was to be recognized—a respiratory catarrh, cough or cold; sore throat or tonsillitis; whooping cough, measles, scarlet fever or diphtheria. Dentition also was listed as a predisposing cause, but in the great majority the otitis was simply the result of a common cold. In about one patient in three, both ears were affected, and in half of these patients, the second ear was affected on the same day as the first.

The signs and symptoms of acute otitis media are pain, fever and an inflamed drum. Deafness is often present, perhaps always so, but is difficult to assess in young children. Earache is the constant symptom; it may last only half an hour or it may keep a child awake all night. There is often some tenderness on pressure over MacEwen's triangle or over the tip of the mastoid process—signals for prompt action. More than half of all my cases subsided and resolved with symptomatic treatment only. In many patients, however, the drum ruptured spontaneously. When it is recollected that frank pus always drained from these ears, it must be admitted that the end-results were remarkably good, for only 12% required a mastoid operation. In an endeavour to improve upon this figure the E.N.T. men of the day demanded that the tympanic cavity should be drained in the early stage by myringotomy. I strove to follow this advice and made great efforts to get these drums incised as soon as they began to bulge, but the results were not encouraging. In my series, primary myringotomy was performed 45 times, 30% of all cases, but the operation, in specialist hands, failed to prevent disease of the mastoid on 8 occasions, and the percentage of success, 37 out of 45, 82%, was certainly no better than that obtained by nature's second method of cure, namely, perforation.

The results to-day show an enormous improvement. Assuredly, acute otitis media is still with us. Logan (1953), analysing the clinical records of eight practices, with something over 27,000 patients at risk from April 1951 to March 1952, found that it was diagnosed in about 3% of that population, but that mastoiditis was mentioned in only 1 in 60 of that 3%. Recent surveys from general practice, particularly that conducted by the Medical Research Council in 1955, show that, although the condition is just as common as formerly, myringotomy is no longer done and a mastoid operation is very seldom required. The incidence of acute otitis media rises up to the age of 5 or 6 years and then falls sharply. 80% of patients nowadays receive sulphonamides or antibiotics in some form—oral, parenteral or local—and residual defects are neither frequent nor serious.

There remain at the present time two questions of very great interest and practical importance. First, what is the explanation of the astonishing improvement in the prognosis for a child who is the subject of acute otitis media? It appears that almost every second child suffers from this disease in early life, and yet myringotomy and mastoidectomy are exceedingly rare. Mastoiditis, like puerperal fever, seems to be a thing of the past. I believe that this remarkable change is to be attributed solely to modern therapy, now so very extensively used. Secondly, what change occurs at the age of 6 years, which cuts the incidence of otitis media by half? Whatever it is, it enables those of us in general practice to continue with confidence to reassure anxious parents that their children will "grow out of it".

LOGAN, W. P. D. (1953) *Stud. med. Popul. Subj.*, No. 7. H.M.S.O.

Dr. David Wheatley: The advent of the antibiotic era has transformed acute otitis media almost overnight from a surgical to a medical condition. At the present time it is mainly treated by the general practitioner. My remarks reflect, therefore, my own views and experience of this condition as I have encountered it under general practice conditions.

The main object of treatment in general practice is to annihilate the infection at the earliest possible moment, thereby allowing the natural processes of resolution to occur unhindered. In the unperforated case, appropriate antibacterial treatment causes such rapid subsidence of inflammation that myringotomy is seldom, if ever, necessary. Often, however, perforation has already occurred before one is called to the case. Nevertheless I have not yet seen a case in which the ear drum has failed to heal and I see some 50 to 100 cases in a year. I have not in any of my cases had a myringotomy performed and in ten years of practice I have not encountered a case of mastoiditis.

The object of antibacterial treatment is simple, but the means of achieving it has been vastly complicated by the glittering array of antibiotics available today. Antibiotics, and I here include the sulphonamides, at the present time may be divided conveniently into three groups. We are not much concerned with the third group, for the main use of these antibiotics is anti-staphylococcal. In general practice we encounter mainly the domesticated strain of staphylococcus and not the wild variant of Fairbrother (1956)

which seems so to infest the wards of our hospitals. The great majority of domiciliary staphylococcal infections remain sensitive to penicillin.

1. Narrow spectrum ..	sulphonamides penicillin streptomycin
2. Broad spectrum ..	chloramphenicol tetracyclines
3. Penicillin substitutes	Erythromycin Spiramycin ("Rovamycin") Novobiocin ("Albamycin") Oleandomycin

In general practice, therapy is blind as indeed it must always be unless perforation has already occurred. Since the infection may be due to a variety of organisms and indeed is often mixed, it is better to cover as wide an antibacterial field as possible. For this purpose I would advocate the synergistic combination of penicillin and a sulphonamide. By this means penicillin is virtually converted into a broad-spectrum antibiotic, yet at the same time retaining its unique bactericidal action, which still excels that of any other antibiotic. The broad-spectrum antibiotics, with their disadvantageous side-reactions and high cost, may then be held in reserve for the rare case that fails to respond to the primary treatment.

I consider that oral penicillin combined with a sulphonamide, provided it is given in high enough dosage, is entirely adequate in this condition (Wheatley, 1953). This is particularly so in general practice as one is dealing mainly with children. It is important to present the patient with a dosage regime that is likely to be adhered to in the home; for we are entirely dependent on our patients for the correct timing of doses. One cannot rely on patients with what is to them a non-serious illness, taking nocturnal doses. Very often also they will not admit to failing to conform to the instructions given them. As a result treatments may be condemned as failures when in fact they were not given a chance. It is only occasionally that the discovery of a half-full bottle of tablets by the bedside, when it should have been an empty one, gives us a clue as to the real cause of failure.

Therefore I give my drugs eight-hourly, a regime which conveniently fits in with the patient's daily routine. This allows doses to be taken on awaking, in mid-afternoon and on going to bed. I have found that this is usually adhered to. As regards dosage, my standard dose for an adult is: penicillin G 500 mg. (800,000 units) (or penicillin V in half this dose) +1 gramme of sulphadimidine, eight-hourly. Children are dosed in proportion and advantage may be taken of the many pleasantly flavoured liquid preparations available.

I last collected my results in 1952, when in a series of 100 cases the following data were obtained (Wheatley, 1952*a*):

TABLE I.—OTITIS MEDIA.

No. of cases	100
Infection subsided	100
Chloramphenicol substituted for oral penicillin+sulphadimidine ..	3
Recurrence in three months	3
Recurrence at longer intervals*	7
Hearing—whisper at 15 ft.+ (follow-up 6–9 years)	100

*Subsequently prevented by removal of T's and A's.

Since then results have been so uniformly similar and satisfactory that I have not needed to record them further.

In chronic otitis media we can enlist the aid of the bacteriologist in determining bacterial species and sensitivities. Nevertheless specific antibiotic treatment is often disappointing, since elimination of one organism so often results in its replacement with another different one. Obviously other factors are concerned and our knowledge of these is obscure. I would like to consider two possibilities, allergy and inflammation.

A persistent discharge after antibiotic treatment, particularly if it is serous in nature and shows only low-grade infection on culture, may be a manifestation of an allergic reaction to the original infection. On this hypothesis it would be reasonable to treat such cases with either antihistamines or steroid hormones. The latter having the advantage of reducing inflammation and making any residual organisms more accessible to a further antibiotic onslaught.

I have in the past given antihistamines both locally and orally to such cases, with some successes (Wheatley, 1952*b*). During the course of such treatment, 3 cases with a persistent

discharge due to Proteus became sterile and I was stimulated to investigate the antibacterial properties of the antihistamine used ("antistin") *in vitro*, with the following results:

TABLE II.—ACTION OF "ANTISTIN" (½%) ON PROTEUS (+ = GROWTH, − = BACTERIOSTASIS)

Time in hours	Dilutions 0	1 : 2	1 : 4	1 : 8	Control culture Nothing added	Control culture Sterile water added
¼	+	+	+	+	+	+
1	±	+	+	+	+	+
4	−	−	+	+	+	+
8	−	−	±	+	+	+
18	−	−	±	±	+	+

Despite this effect, however, the treatment failed to eradicate Proteus in subsequent cases and I have not pursued this line of investigation. Recently I have had some better success with the local application of hydrocortisone and hydrocortisone+neomycin drops.

Nevertheless chronic otitis media remains a fairly difficult problem in general practice where lack of time and facilities contribute to a need for some fairly simple home therapy.

Mr. S. R. Mawson referred to the possible importance of teething as an ætiological factor when it occurred concurrently with an infection of the middle ear.

Most textbooks had little to say on this but in Wilson's recent book "Diseases of the Ear, Nose and Throat in Children," the opinion was given that the connexion between teething and otitis media was "merely an ignorant superstition". Was this true?

In hospitals, infants were seen with acute or recurrent otitis media in whom it appeared that the only concomitant with any possible ætiological significance was the eruption of teeth.

He had collected 32 cases—admittedly a small series, but in these he was sure that there was no other precipitating cause. Each seemed to be a primary otitis media associated solely with erupting teeth. In December last he sent a questionnaire to the mothers of these children inquiring whether there had been any subsequent earache or discharge and if so what was considered to be the cause. 15 had replied, but in only 2 had there been any subsequent earache and discharge and both had been attributed to severe colds, so that 13 out of 15 had had no further trouble with the ears since that connected with teething. The period of follow-up ranged from half to two and a half years after the cessation of teething and it seemed significant that in this period 86% were free from ear symptoms. In his own experience, he would say that teething undoubtedly did involve some infants and children in otitis media. While the exact mechanism had yet to be explained, there would still seem to be a sound position to defend against the extreme charge of "ignorant superstition". As to treatment, he felt that each one needed to be treated as otitis media on its own clinical merits.

Mr. A. G. Tresidder spoke in defence of the operation of myringotomy which was used before the advent of antibiotics when dealing with the case of a child with a red bulging drum. True, the operation did not always prevent a subsequent mastoid operation. Nowadays, such a condition of the middle ear was almost universally treated by antibiotics and in a large number of cases the bulging and redness disappeared and apparently the hearing was restored, but it had been suggested that the absorption of the exudate in the middle ear led to some fibrosis round the ossicles and might be a cause of deafness in after years. He felt himself that when one was confronted with a red bulging drum myringotomy should be carried out to see what the organism was and the appropriate antibiotic given.

Dr. L. Roodyn discussed recurrent otitis media associated with enlarged adenoids which was a particularly common condition in children between 5 and 7 years of age. Recurrent hæmolytic streptococcal infection of the throat with spread to the middle ear accounted for some of the cases, but a greater number were probably caused by virus infections. At the Meeting on Adenoviruses of the Pathology and Epidemiology Sections held on January 15, 1957 (in press), Dr. H. Pereira of the Common Cold Research Unit, Salisbury, described a small outbreak of these infections which occurred in the families of some of the laboratory workers. One of the boys who was about 5 years of age had a typical adenovirus infection and some four or five months later his adenoids were removed. It was possible to cultivate from the adenoid tissue removed at operation the same type of virus.

This observation which showed that the adenoviruses persisted in the adenoid tissue for several months, suggested that the overgrowth of this tissue may represent a hypertrophic reaction of the lymphoid tissue to the continued presence of the virus.

The recurrent otitis media was probably caused by the mechanical effects of a pad of hypertrophied adenoid tissue or perhaps there might be direct infection of the middle ear by the adenovirus.

Whether the removal of the adenoids significantly reduces the recurrence rate of otitis media is still undecided.

Mr. S. W. Allinson said that there should be a prophylactic approach to diseases of the ear, nose and throat. The baby should be taught to breathe through the nose with the mouth shut. The mother should press up baby's chin to close the mouth and so encourage breathing through the nose. The nose should only be blown gently and never pinched.

If, in later life, a patient should be seen complaining of attacks of otitis media then in the first place breathing through the nose with the mouth shut should be taught and the nose should only be blown gently.

If these methods fail it may be necessary to remove the tonsils and adenoids but this operation should rarely be necessary in the first instance.

Dr. G. O. Barber said that he was interested, when Mr. Lionel Taylor was going through his causes of otitis media, that there should be no mention of the significant number connected with the onset of measles. Twenty-five years ago an attack of measles was very often coincident with an attack of otitis media and he wondered why they did not think of it nowadays as such an inevitable complication. Had something happened to measles to prevent this complication? Had a social change taken place with regard to measles? Twenty-five years ago quarantine was extremely strict and everything was tried, to postpone the onset of the exanthem until the patient was older and had gone to a residential school.

He was reminded of 1935 when out of a possible 340 boys there were 96 cases of measles of whom 76 were in the sanatorium at once, and it was a sanatorium designed to hold a maximum of 56 cases which meant that it was grossly overcrowded. At the same time there was a virulent hæmolytic streptococcus in the school causing sore throat and out of the 76 cases 40 developed acute otitis media.

Like Dr. Abercrombie in those days he too was under the influence of the myringotomist and he and his partner used to go along the moment a boy reported earache, and perform a myringotomy. They did 40 myringotomies and there were four mastoids; this was the same percentage as Dr. Abercrombie's.

In the follow-up of these boys, the majority had a second or even a third attack during their three or four years at school. The acute attack during measles seemed to establish a tendency to recurrent otitis media.

The **Chairman** said that he thought the virulence had decreased in scarlet fever as well as in measles. One used to find that the drum head went in a few days, one never saw that nowadays. He was surprised at the number of people who had had measles before they went to school, did Dr. Barber say that 3% had not had it?

Dr. Barber said that nowadays the majority of the boys in the senior school had had it, 3% of boys had not had measles.

Mr. F. C. W. Capps said he could remember as a young patient in the pre-antibiotic days having to wait a week for the drum to burst; and if ever the antibiotics or the sulphonamides failed in efficiency he hoped that the general practitioners would remember that myringotomy was still a very good procedure. It was a good rule "where there is pus let it out", especially in the presence of pain.

Mr. G. H. Bateman said that the main indication for myringotomy was pain which was not relieved quickly by antibiotics.

Mr. J. F. Lipscomb made the point that general practitioners should test the patient's hearing and not rely on purely clinical symptoms. One has often to do a myringotomy two to three weeks after the initial attack of otitis media because of persistent deafness.

Dr. R. Goulding said that the previous speakers' questions as to the general use of antibiotics were important. They had heard from the general practitioners present what they did and how they did it, but he would point out that those who had come to the meeting were the enlightened ones. He had done a number of locums and had come to the conclusion that a vast quantity of antibiotics used for otitis media was ineffective because the routes of administration and the doses employed were neither appropriate nor adequate. He was beginning to wonder whether this great improvement in the course of otitis media over the last ten or fifteen years was due to antibiotics or whether it was due to a change in the natural history of the disease. Although it would take a great deal of courage, it would be interesting

to study two parallel series of patients, one given antibiotics and the other treated by conservative methods alone, and see just how much difference there would be in the results.

Dr. L. W. Batten said that with regard to myringotomy he would like to agree with Dr. Abercrombie that early incision was bad, one should wait until pus was present. It did not relieve pain very often and certainly did not stop pus forming. It was good sense to let the pus out, but nowadays it was not often there.

Mr. J. W. S. Lindahl said that otologists in the hospital saw the patient once and not always again, and it was sometimes difficult to assess the effect of removal of adenoids on recurrent otitis media. It seemed that by the removal of adenoids the process of recovery was initiated and that the cause of recurrence was not only obstruction but some degree of infection of this eustachian tube and surrounding tissues.

Frequently there would be another attack or two of otitis media after the operation and he warned mothers that they might expect this. He could produce no figures at all, but it was his impression that the number of attacks of otitis media after operation were almost in proportion to the number of attacks before. There was a hard core of cases which went on and on but there was also a majority who got better and one did not necessarily know about them as they were not always brought up again.

Mr. Lionel Taylor, in reply, said that there were three points; the first one was Dr. Barber's mention of measles. His table showed the causes of *recurrent* otitis media but he agreed that measles was a predisposing cause of acute otitis media. Secondly, his impression was, in spite of what Mr. Lindahl said, that generally if the adenoids were adequately removed—he used that word advisedly—the fall in the incidence of otitis media was most marked. He had seen it in his own family and probably all of them had seen it in theirs.

He thought Dr. Roodyn was a little unlucky in some of his cases, he might have had a larger number than average of the "hard core" children who went on getting otitis media.

The third point was Mr. Tresidder's—what one did when one was faced with a red bulging drum? As Mr. Capps had said, with a general anæsthetic and a myringotomy the result was dramatic and the course of the illness was shortened very considerably. Having done a myringotomy the progress of the infection was apparent. One had only to look and could then see if there was any more pus coming out and one knew that the child would not develop a latent mastoiditis. If the child was given penicillin, however adequate the dose, there was a chance that he would develop one of those rare mastoids and mastoidectomy would have to be done.

Dr. D. Wheatley said he was a little disturbed by the speaker who said he had to wait for his drum to perforate, that might have happened years ago but if he went to his general practitioner nowadays he would be treated with antibiotics and the infection would be gone long before the week was out. Those who stressed the diminishing virulence of the streptococcus for the improvement of results really did not believe what they said! An admission had been made that few would be prepared to put up a control series with and without antibiotics.

The Chairman said that as a result of the discussion he remained convinced of the potency of antibiotics in ear disease but he was also convinced that adequate doses must be given.

DISCUSSION ON THE AFTERMATH OF HYSTERECTOMY AND OOPHORECTOMY

Dr. Katharina Dalton: Not all hysterectomies end in tragedy, but a great deal can be learnt from those which do. The sooner the after-effects of this radical operation are fully understood the more will the importance be realized of considering every possible alternative treatment before the final decision to perform a hysterectomy is reached. To study the long-term effects of this operation a questionnaire was used to follow up all cases in my practice. This practice is not representative of general practice, but is overloaded with sufferers from premenstrual syndrome and menopausal disorders. It is, therefore, not possible to compare this series with controls and no claim is made in this respect. In this series, of the 43 women 6 were single and 3 widowed. Of the 34 married women 3 have since obtained divorces and a further 12 have sought the advice of a marriage guidance counsellor in an effort to prevent marital disruption. Thus in 44% of married women in this series hysterectomy has been followed by marked loss of marital happiness. Undoubtedly in many cases marital discord may have been evident before hysterectomy, but this vital event in the lives of a married couple may possibly prove the last straw. The husband, who cannot and knows he never will be able to enjoy sexual satisfaction with his marriage partner, has a greater temptation to seek the company of another woman. Nevertheless the marriage may have been on an even keel prior to hysterectomy.

The three divorced women all reported normal intercourse before operation, but intercourse had not been attempted since. Before operation 76% of the married women experienced normal intercourse, and the remainder reported unsatisfactory intercourse due to dyspareunia or infrequency. However, after the operation only 22% reported normal intercourse, 36% reported unsatisfactory intercourse and in the remaining 42% there had been complete abstention. This question was often answered by a look of surprise or such statements as "I didn't know I could" or "I thought I was all sewn up". One replied "Oh no, my husband is too thoughtful", but alas! one year later the thoughtful husband was enjoying the company of his secretary. Surely there is a failure here in pre-operative preparation and post-operative guidance in omitting discussion on this very important subject with husband and wife.

When asked if they were pleased with the result of the operation 23 of 43 women replied "No". Some amplified their statement with such remarks as "I feel pain more now", "I worry over trifles", "Never really well", "Don't like company", "It made me hard", "I always wanted children" or even "I've a lovely scar, but my health has never been the same since". In contrast the reason given by those who were satisfied was always the same "No worries about becoming pregnant". This suggests an insufficient knowledge of contraceptive measures and possibly too little faith in them, or that while believing it is morally wrong to use contraceptives, they are conscience free if gynæcologists render them permanently sterile.

Analysis of those who were satisfied with hysterectomy showed that they were equally shared among the married, single and widowed, but there was a marked difference in satisfaction according to the time that had elapsed since the operation. Thus, less than one year after operation 83% were satisfied, but between one and five years only 41% were

satisfied. The figure dropped to 33% for those six to ten years, and rose to 50% after ten years. These figures may account for the impression among gynæcologists that their operation has been successful, for they often see the patient for a final examination two to six months after leaving hospital, at a time when she is still happy with her recovery from a major operation but before she has returned to the full stresses and strains of everyday life, and before intercourse has been seriously attempted.

The age of the patient at the time of hysterectomy appears to affect the success of the operation. Of those who were under 40 at the time of operation 70% were satisfied, between 41 and 45 years only 43% were satisfied, dropping to 25% for those between 46 and 50, and 40% between 50 and 55 years. It is only those over 55 who give the pleasing figure of 100% satisfied with the result of the operation. This suggests that Nature objects most to interference by hysterectomy when this is performed at the time of the natural menopause.

Analysis of the extent of the operation revealed that 55% of those who underwent simple hysterectomy were satisfied, 50% of those who had hysterectomy with removal of one ovary were satisfied, but only 20% of those who underwent hysterectomy with bilateral oophorectomy were satisfied. This confirms the recognized teaching that the ovaries should be preserved if at all possible. Only two women underwent subtotal hysterectomy, so no comparative figures for this and total hysterectomy can be given.

Was the incidence of neurosis high after hysterectomy? 74% of the women were troubled by recurrent headaches. In half of these women headaches had been noted to occur premenstrually before operation, but the post-hysterectomy headaches were increased in intensity, often accompanied by vomiting, photophobia or blurred vision. Vertigo was a recurrent symptom in 60%, hot flushes occurred in 68%, rheumatism in 50%, lethargy in 57% and depression in 62%. Thus the presence of six common neurotic symptoms occurred in over half the women. Charts of some members of this series showed how these neurotic symptoms recurred cyclically at the time of the menstrual equivalent (Fig. 1).

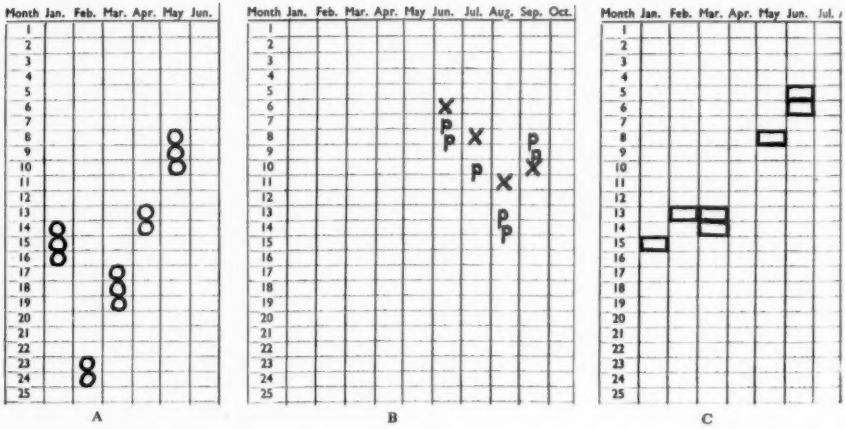

FIG. 1.—A, Patient aged 50, para-1; hysterectomy for fibroids at the age of 45. ○ = headache. B, Patient aged 48, single; hysterectomy and bilateral oophorectomy at age 45. X = giddy; p = abdominal pain. C, Patient aged 47, para 5; hysterectomy five years ago for menorrhagia. Bilious attacks occurred with periods. ▭ = bilious attacks.

Headaches and vertigo occurred at twenty-four to thirty days' interval and were accompanied by lethargy, depression and tension. Fortunately these cases of cyclically recurring symptoms respond excellently to progesterone or ethisterone, and in this series 22 women were so treated. The dosage of progesterone required to render these patients symptom-free is on the whole higher than among normal sufferers from premenstrual syndrome. One professional woman with heavy responsibilities is to-day leading a life filled with social engagements on a dose of 75 mg. progesterone daily; previously she was afflicted with migraine and depression and lived only for the day when she could retire at 55 years

and spend her whole day resting. Hot flushes are recognized as a menopausal symptom which responds to œstrogen therapy, and again, the late Dr. Joan Malleson (1955) reminds us that relatively large doses of even synthetic œstrogen preparations may be needed to correct the hormone balance. In the light of these facts it would appear that these multiple symptoms are due to endocrine imbalance rather than neurosis.

Excessive weight gain is another troublesome symptom. In this series 50% noted a gain of 1 stone within a year of operation, and 35% noted a gain of 2 or more stones within this space of time. Increases of 3, 4, and even of 5 stones during the first post-operative year were recorded. An acute weight gain occurs during the first two or three months and is followed by a gradual but persistent rise. The obesity is chiefly of the water retention type responding rapidly to fluid and salt restriction, diuretics and dieting. This regime should be instituted as soon as post-operative weight increase is recorded. Green-Armytage's (1955) advice is for a low fat diet following hysterectomy as "the incidence of coronary atherosclerosis in castrated females approximates that in males, a ratio normally in the region of one in ten".

For what reasons was hysterectomy performed? Or, more important, could hysterectomy have been avoided? This series undoubtedly included a few examples where this operation could have been avoided, or should have been the last resort after other methods of treatment had failed. The causes in this series were fibroids 17, menorrhagia 14, ovarian cyst 9, endometriosis 4, missed abortion 3, post-menopausal bleeding (Stilbœstrol) 2. Multiple causes were noted in 5 cases. The fibroid was an accidental finding in 4 cases, while attending for infertility 3 and for contraceptive advice 1. In exactly half the cases of menorrhagia no alternative treatment had been tried or suggested. There are occasions where hysterectomy is undertaken because of a low hæmoglobin, but iron deficiency anæmia due to malnutrition can, and does, occur in menopausal women as well as in other ages. Nor must it be forgotten that a lay person, who has only seen her own individual menstrual loss, is often unsure how to answer the question "Are your periods heavy?" To enquire into the amount of sanitary towels used is fallacious, merely giving an index of the fastidiousness of the patient. It is the degree of soaking of sanitary towels which is significant, and in these days of cheap polythene bags it should be possible to inspect personally all towels used in cases of suspected menorrhagia. A plea is also made for the more universal use of menstrual charts to verify the patient's statement as to duration of loss and length of cycle. Nor should a single hæmoglobin estimation suffice for the diagnosis of anæmia due to menorrhagia. Indeed, the hæmoglobin may be down premenstrually, due to water retention causing hæmodilution, and rise after menstruation. Water retention can be demonstrated by weight gain, and this premenstrual water retention will respond to the use of diuretics and progesterone (Fig. 2). Can one justify a diagnosis due to blood loss if the anæmia improves after the blood loss?

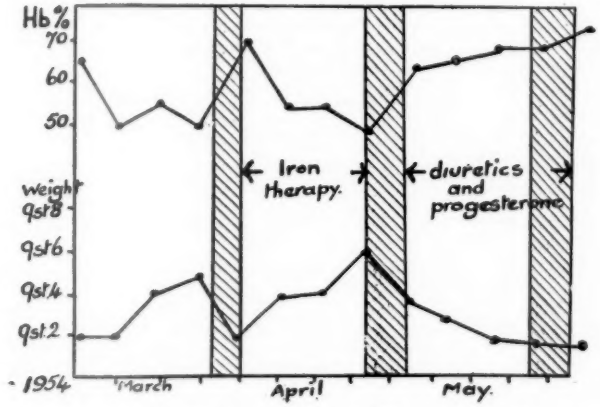

FIG. 2.—Aged 42 years. Para 6. ▨ = menstruation.

Can the aftermaths of hysterectomy be avoided? It is suggested that if their presence is

anticipated and appreciated then they can be avoided. There should be a careful selection of cases by attempts at alternative treatments. It is for the gynæcologist to decide in individual cases whether radiotherapy could be a possible alternative. Myomectomy still has a place in surgery. Curettage should not be forgotten. Hormone therapy and psychotherapy also have their uses. Utriculoplasty is of interest. This consists of resection of a portion of the uterus; uterine function is maintained and bleeding is reduced as the area of the endometrium is reduced.

When the decision to perform a hysterectomy is reached the pros and cons of the operation should be impartially presented to both husband and wife. The patient should know which symptoms she may expect to be alleviated by this operation. Floodings will cease; dysmenorrhœa will go; sterilization will be permanent. Headaches, depression and other accompaniments of menstruation will continue to occur cyclically; hot flushes will become more acute. There may be a weight gain of 1 or 2 stones within a year. Dyspareunia will not improve, but hysterectomy may be a convenient excuse for total abstention.

Post-operatively the path of the artificial menopause will be eased by discussion and simple psychotherapy, while the alleviation of unpleasant symptoms with hormones may be necessary. The weight gain should be noted, and, when required, advice on dieting given. The reference of patients after hysterectomy to an endocrinologist for observation is worthy of consideration. But primarily, let us recognize that there are aftermaths and that prevention is always better than the cure.

Dr. G. J. V. Crosby: I have recently been considering some of the disturbing effects of oophorectomy in a short sequence of patients observed in my own practice. My indignation reached its acme, when I listened to the history of a single woman of 52 living alone. In 1934, at the age of 30, this patient complained of irregular and profuse bleeding suggestive of uterine fibroids and this diagnosis was ultimately made. At the time, she was engaged to be married and all seemed "set fair". The implications of operation were put to her and to her fiancé and it was pointed out that she might well have to lose her uterus, though nothing seems to have been said about removal of the ovaries. At operation, the fibroid uterus was completely removed. Her ovaries were considered suspect and bilateral complete removal was performed. The histological report was to the effect that there was no sign of malignancy.

We all of us appreciate the physical and the psychological phenomena of the natural climacteric. Perhaps it is not so usual to recognize the devastating impact of an acute onset of menopausal symptoms in a woman below 45 years of age; symptoms which we know to be directly attributable to an endocrine imbalance due to loss of ovarian hormones. This leads to uncontrolled and increased secretion of the gonadotrophic hormones which are thought to be the cause of flushing, sweating, increase of weight and ultimately hyperthyroidism and hyperadrenalæmia (hypertension and hirsutism).

The group of symptoms directly attributable to loss of œstrogens and resulting in vulval and vaginal atrophy, take longer to make themselves felt, but pruritus vulvæ and dyspareunia can be particularly distressing. These are probably more easily controlled by the administration of ovarian hormone, especially œstrogen. In the "classical" case which I am describing, there was apparently a rapid appearance of symptoms which not only made life thoroughly uncomfortable, but which also induced a psychological disorganization exhibited by bad-temper, irritability, loss of sexual interest and libido; and this, in spite of regular administration of œstrogens—in those days in the shape of monthly courses of Menformon, the dose of which is unfortunately not recorded. The engagement was ultimately called off; alcohol was taken in toxic quantities with all the significant and depressing results to be expected therefrom, and a promising happy life was utterly broken.

The effects of oophorectomy are not entirely reversible by hormone therapy and there may be some danger that this is overlooked when removal of the ovaries has to be considered. Therefore, every step should be taken to save as much ovarian tissue as possible, even to the extent of submitting the patient to a second operation (the first being a simple biopsy)—a procedure which may at the time seem drastic if not unjustifiable. I

understand that the small warty excrescences ("papillomata") so often seen on ovaries of normal or near-normal size are seldom, if ever, malignant.

In the United States two very long series have been analysed during the past six years. Doyle (1952) investigated a list of 546 patients from whom as many as 704 normal ovaries had been removed. Of these victims, only 5·1% were found to be carcinomatous. 56·8% had fibroids, 20·5% cystic ovaries, 8% so-called endometriosis and the remaining had lost their ovaries for reasons ranging from ectopic pregnancy to dysmenorrhœa and functional bleeding.

The total ablation of the ovaries must be followed by the disabilities of a natural menopause, but these are always intensified and more distressing the younger the patient. It is only too easy to assume that, in these days of hormone substitution therapy, the easy course of bilateral extirpation may be adopted without serious results. This is always a fallacious assumption and it is the general practitioner who sees the proof; but as general practitioners, the treatment of these symptoms by the administration of hormones is our responsibility. The symptoms must be divided into two classes: (1) those due to loss of the œstrogenic substance, including pruritus, dyspareunia, kraurosis and (when the uterus is retained) vaginal discharge and irregular bleeding; and (2) those due to hyperfunction of the anterior lobe of the pituitary, including flushing, sweating, and obesity—with the more distant possible effects of hyperthyroidism and hyperadrenalæmia. Obviously, the first of these groups requires the exhibition of œstrogens (and personally I like ethinyl œstradiol in small doses) while the second class demands the addition of testosterone which, I believe, the endocrinologists claim has a "braking" effect on the anterior pituitary. I might here mention a recent case, a woman of 42 who has had bilateral oophorectomy for carcinoma, but who has retained her uterus because there were abdominal deposits which made hysterectomy useless. Her most trying complaint has been that of vaginal discharge. Testosterone has had absolutely no effect upon this, though her other symptoms have recently improved. In view of the malignancy, administration of œstrogens has been discouraged, but I feel that otherwise this would probably be the rational approach.

Obesity may well yield to dietetic measures and in this it is, I think, strictly comparable with the obesity of the normal climacteric. In the same way, water retention and migraine probably demand progesterone plus salt and fluid restriction.

Unilateral ablation and even partial removal may be performed with far greater facility than that of total extirpation—for a cyst, for painful ovary (possibly simulating appendicitis, when both appendix and ovary may be improperly removed), for an ectopic pregnancy, in fact for a large variety of reasons. Even here we should press for the most extreme degree of conservatism which is safe and possible. It seems to be generally accepted that as long as some ovarian tissue remains, all will be well; I am not so sure. I recently saw a woman of 35 whose gain in weight following a simple unilateral oophorectomy for a small cyst was quite unbelievable—well over 30 lb. in just over a year. At the same time, menstruation had become irregular. Béclère and le Corvaisier (1953) suggest that the initial general reduction of ovarian secretion stimulates the pituitary to excessive gonadotropic hormone production with ultimate œstrogenic hyperfunction of the remaining ovary. This combined pituitary and ovarian action might well produce a syndrome such as I have described. The patient, in this case, is taking off some weight by diet alone. I suppose the administration of testosterone or progesterone would be the next rational step, but I doubt their clinical value. In this I find myself in agreement with Bishop (1956) who has largely discounted the importance of glandular substitution in the treatment of obesity generally—including that associated with the menopause.

Even unilateral oophorectomy may have a profound psychological effect. Knowledge of interference in any shape or form with the ovaries may well produce a fear of sterility. As a case in point, a woman of 34, recently married, in possession of the left ovary only, failed to become pregnant at as early a date as seemed desirable to her and her husband. A search for a cause for this assumed sterility was instituted, with negative results up to the time of a salpingogram which showed the left tube to be blocked and the right tube patent. These findings caused extreme despondency, the patient coming to regard herself as no longer of any use as a woman. However, continued effort has resulted in pregnancy and the fact that only one ovary is available is now forgotten.

Mr. John Beattie: Gynæcologists are still divided on the subject of removal of healthy ovaries when a hysterectomy for innocent conditions is performed at the age of 40 and onwards. Although removal of both ovaries during pelvic surgery in women over 40 would save a few cases of carcinoma developing later on, the disadvantages of castration in these cases are enormous and I am emphatically in favour of preserving ovarian function whenever possible and at least up to the age of 50 or over. Richards (1951) and Barcroft-Livingston (1954) have shown by different methods that if a hysterectomy is done with preservation of the ovaries by a careful technique, menopausal symptoms need not occur for a long time afterwards and in some cases a normal menopause occurs years later. It is most important to preserve the ovarian blood supply and not to drag the ovarian pedicles into the centre of the pelvis with a purse-string suture. Figures show that removal of both ovaries before the age of 45 produces hot flushes in 98% of cases. This figure is reduced to 52% when one ovary has been removed and to 27% when both are retained.

Hysterectomy should always be total unless there are complications present which make a subtotal operation safer. The subtotal operation has an aftermath of its own. If carcinoma develops in the cervix after subtotal hysterectomy it is difficult to deal with. A multiparous cervix is often infected or eroded and discharge continues after a subtotal operation. Cervical polypi may arise in the cervical canal and cause bleeding and discharge. The aftermath of total hysterectomy is as follows: (1) The occurrence of dyspareunia if the vagina has been shortened. (2) The development of granulations at the vault of the vagina which produce bleeding and discharge, especially after coitus. The treatment is by one or more applications of silver nitrate to the area. (3) A patient who develops vaginal prolapse after total hysterectomy may require a special operation to cure this and to support the vaginal vault. (4) Occasionally a patient complains that loss of the cervix has affected her libido during coitus but an assurance that a possible cancer-bearing area has been removed should be enough to satisfy her.

Hysterectomy is now more often advised than some years ago because: (1) An artificial menopause produced by X-rays or the insertion of radium into the uterus does not protect the uterus from the development of carcinoma later on. (2) A patient who bleeds excessively at the menopausal age is often suffering from an endometrial hyperplasia, and if this is present carcinoma of the body of the uterus is more likely to develop in later life. (3) An irradiation menopause as an alternative to hysterectomy may lead to the sudden onset of hot flushes and other symptoms which may be severe and prolonged. (4) Despite intensive research on hormone therapy in relation to irregular menopausal bleeding, the results are extremely disappointing in patients who are in the late 40's.

It is essential when a hysterectomy is advised to spend some time explaining in detail to the patient and her relatives: (1) what the sex glands are in relation to the uterus; (2) that the uterus only has two functions, i.e. for the purpose of childbirth and if fertilization does not occur to cast off the lining each month; (3) that intercourse will proceed as before; (4) that the patient should have the same sexual feelings as before.

Removal of the uterus in certain circumstances can have a most fundamental and deleterious effect upon a woman. This particularly applies to the patient who is nulliparous or unmarried at whatever age the operation becomes essential. The effects are likely to be more serious if hysterectomy becomes necessary in the 30–40 age group but may also be profound even in the late 40's. The serious psychic consequences occur because a woman has been deprived of her capacity to bear children even if there has been no opportunity of doing so in the past and even if the woman has reached an age when childbearing is impossible. This feeling of potential capacity for childbearing does play an immensely important part in a woman's life.

The ill-chosen case and the hysterectomy performed without every effort being made to avoid the operation if possible may well lead to a mental upset which varies widely in type from a mild neurotic state characterized by anxiety and depression to hypochondriasis with aches and pains, and fears about the body, accompanied by severe depression.

There is a particular complication associated with hysterectomy which seems to have been unrecognized previously. Dr. Ida MacAlpine (personal communication) found that women complaining of intractable pruritus vulvæ, alone or in combination with pruritus ani, almost invariably revealed a history related to accidents in childbearing, such as miscarriage and stillbirth or to abdominal operations including hysterectomy. In over 80 cases thus investigated during psychotherapy these factors played a far more important part than lack of sexual satisfaction, to which pruritus vulvæ is commonly attributed. In 28 cases of most severe pruritus vulvæ a hysterectomy had been performed in 7 (25%).

There is no doubt at all that hysterectomy with conservation of the ovaries when carried out for the relief of severe symptoms untreatable by other methods is a great success. If the patient is in the fourth decade of life, is well adjusted but greatly inconvenienced by her symptoms she will welcome the removal of the uterus. It is important to be extremely conservative in the younger age group and avoid hysterectomy unless it becomes absolutely necessary. Hormone therapy should be persevered with in cases of functional uterine bleeding, myomectomy should be done for fibromyomata whenever possible, and conservative surgery adopted for the treatment of endometriosis.

The aftermath of oophorectomy.—Conservative ovarian surgery in the childbearing period of life is essential. Even in the late 30's and early 40's removal of both ovaries is a disastrous step. Only in the case of malignant disease should this be done. In cases of endometriosis and inflammatory disease in the pelvis, if operation is essential, as much ovarian tissue as possible should be preserved.

At the natural menopause about 75% of women will have some, if minor, symptoms but less than one-third of these will require œstrogen therapy. A much higher incidence of menopausal symptoms will follow removal of the ovaries or a castration dose of X-rays or radium before the natural menopause has occurred. These symptoms will be much less severe in the energetic and active extrovert who has never had time to dread the change of life and who may even look forward to the cessation of menstruation. The opposite to this is the woman who dreads the menopause as the end of everything. Such patients will be irritable and suffer in an exaggerated form from the fear of growing old, from a contracting social circle and from the death of relatives and friends, the children growing up and leaving home; there may also be anxiety over the economic background to their lives. All these troubles can be analysed and controlled by the stable and intelligent woman but they assume overpowering proportions in the unstable person. The main symptoms of an exaggerated menopause comprise the sympathetic storms of hot flushes and perspiration, the amenorrhœa and the atrophy of the genital organs. This triad may produce a severe psychological upset if the woman who is growing old does not develop fresh interests. She feels she is no longer attractive, the best of life is over, tension and anxiety develop and fear aggravates the autonomic instability of the menopause. With this dysfunction of the mind and body, obesity, peripheral pain, hypertension and osteoporosis may develop.

Before œstrogens were used in clinical medicine women who had menopausal symptoms were treated with bromides and valerian or small doses of phenobarbitone, and sooner or later the hot flushes and sweats were relieved. Œstrogens are not always entirely successful in curing patients of menopausal symptoms. It is most important to administer œstrogens in cyclical doses and never continuously and an effort should be made to find the minimum dose which will relieve the symptoms.

Bilateral oophorectomy is being done in increasing numbers for cases of carcinoma of the breast, relying upon the fact that a certain number of such carcinomas are hormone-dependent. Menopausal symptoms following this treatment are better alleviated by the male hormone than by œstrogens.

The use of a combined dose of œstrogen and androgen is often advocated as the two probably have a synergistic effect in controlling secretion from the pituitary and the androgen may act as a deterrent to the possible carcinogenic action of unbalanced œstrogens. The doses suggested are ethinyl œstradiol 0·01 mg. and methyltestosterone 5 mg. to be given in a cyclical manner.

Weight reduction is important from both the psychological and physical point of view and in this small doses of thyroid will be of help in the hypothyroid patient. A reduction in fluids and salt intake often helps to lessen the retention of fluid which may occur in the early days of the menopause and when œstrogens are being administered.

Mr. Aleck Bourne was surprised to hear of the large number of serious disabilities which followed hysterectomy, as reported by Dr. Dalton. He has always regarded the operation, when performed for adequate indications and with conservation of the ovaries, as one of the most successful in surgery for restoring a woman's health. He emphatically endorsed

the opinion of Dr. George Crosby on the malign effects of removal of both ovaries before the age of 45, or even later, where there was no destruction thereof by serious inflammatory or malignant disease. Enucleation of simple cysts and dermoids was nearly always possible with retention of normal ovarian tissue.

Professor W. C. W. Nixon emphasized the importance of conservative surgery in gynæcological conditions. He agreed with Dr. Dalton that even after a hysterectomy, with conservation of the ovaries, psychological disturbance of varying degrees of severity might follow. A recent anatomical investigation by a Swedish gynæcologist had shown that the ovaries in a number of patients receive their blood supply mainly from the uterine artery. Thus a hysterectomy in such patients might interfere with the blood supply to the ovaries and ovarian atrophy would follow. He reminded the meeting of the success that Mr. Aleck Bourne had had in the operation of utriculoplasty for the treatment of menorrhagia of emotional origin.

Mr. Frank Musgrove said that when the operation of hysterectomy and oophorectomy was contemplated, the gynæcologist, whenever possible, should interview both husband and wife together pre-operatively.

At this interview, he should point out what the operation entailed, viz. an absence of the menstrual period and the onset of symptoms of the menopause, at the same time explaining that marital relationship should not be interfered with and that the effect of the loss of the ovaries can be replaced by oral administration of specific hormones.

In the summary of investigations and treatment sent to each general practitioner on the discharge of the patient, advice should be given that œstrogen-substitution therapy should be prescribed for all patients, in definite courses, for a period of at least six months, provided that malignancy has been excluded.

In following up several hundred cases of hysterectomy and oophorectomy, it was noted that in only 2% of cases was post-operative œstrogen-substitution therapy given by the general practitioner concerned.

Dr. E. Robert Rees completely disagreed with the very tragic picture that had been presented by the opening speaker. Were this a true reflection of the effect of hysterectomy, surely it would long ago have become a terrifying prospect to anyone. He firmly believed that these dreadful consequences could be prevented. It was insufficient merely to tell the patient that she would not be affected by this operation; it was essential that she be convinced of the truth of this. He adopted the attitude that unlike other forms of surgery, the patient losing a uterus, loses something that is not essential to her day-to-day metabolism or other body processes—unlike those others who have to lose their gall-bladder or some other essential structure.

He then pointed out to them that coitus in the common domestic animal was chemically controlled and therefore confined to ovulation times. This was not so in the human where the emotional factor was all-important. He pointed out to them that coitus took place during the early months of pregnancy in about 70% and usually continued after the menopause when the uterus ceased to be an actively functioning organ. These arguments nearly always succeeded in convincing the patient that the uterus was merely a box where a new lining was prepared each month and that when it caused distress or discomfort, its removal resulted in relief, with no disadvantages.

In conclusion, he stressed that it was the gynæcologist's duty not only to give the reasons for hysterectomy but also to make it quite clear to the patient that there should be no dreadful consequences from this operation. And he added that it was equally easily understandable that such consequences could and did result if the patient was not convinced to the contrary.

Dr. A. R. L. Abel drew attention to the possibility of using male hormone in cases of secondary carcinoma of the mammæ in very much larger doses than had been mentioned. It was not always possible to tell which cases were going to be suitable for such treatment, but laboratory tests were now being evolved which would show exactly in whom some improvement could be expected, and doses of up to 1,000 mg. of testosterone might be given with most startling and satisfying regression of secondary deposits in a very few cases.

BOOK REVIEWS

The Sexual, Marital and Family Relationships of the English Woman. By Eustace Chesser, M.D., in collaboration with Joan Maizels, Leonard Jones, B.Sc., Ph.D., and Brian Emmett, B.Sc. (Pp. xxxvi + 642; illustrated with many tables and charts. 75s. 0d.) London: Hutchinson's Medical Publications. 1956.

This monumental tome, referred to on the dust cover as "The Chesser Report" and running to 642 pages, is a statistical survey of the replies given by 6,500 married and single women to a questionnaire distributed more or less at random by 1,500 family doctors. It is, in effect, an English version of the earlier American Kinsey Report though it does not slavishly follow its predecessor.

The aims of the survey, as given by the authors, were (1) to discover the experiences in, and attitudes towards, marriage and sex relationships of English women, (2) to trace the association between certain childhood experiences and these relationships, and (3) to discover the factors associated with their feelings of happiness or unhappiness in marriage.

In order to achieve their results the authors compiled six different questionnaires, three for married and three for single women, and the major portion of the work consists of statistical analyses of the answers in the form of tables and graphs with associated commentary or amplification. There are innumerable cross references to matters which are considered to be of significant relevance. No fewer than 479 tables and 81 charts summarize the information and one quickly becomes lost in trying to extract some meaning from the welter of figures or draw some conclusion from the data given.

This work is essentially academic and one for the specialist in Sociology. The average doctor will find little practical use for the abundance of statistical information even if he has the time to plough through it.

One thing the work seems to confirm is the necessity for ensuring, in the interests of subsequent happy marriage, that children's early years are as happy and secure as possible. The figures emphasize that enlightened and sensible parenthood and intelligent sex education are essential to this end. As Dr. Chesser remarks in his summing up at the end of the book: "Only too often a vicious circle is created. A child may be starved of love because its parents are unhappily married, and no amount of legislation can give it the security for which it craves. If we look for the reason why the marriage is a failure, we may find it in the early childhood of both parents. Because they were deprived of love as children they are incapable of a satisfactory love-relationship as adults, and history repeats itself in their own child, and may be endlessly repeated in their descendants." If this book helps to prevent such perpetuation the writing of it will have been well worth while.

Diagnosis and Treatment of Peripheral Vascular Disorders. By David I. Abramson, M.D., F.A.C.P. (Pp. xv + 537; illustrated. £5 5s.) London: Cassell & Co. Ltd. New York: Paul B. Hoeber, Inc. 1956.

This book is written for "the busy family physician". It has three parts. The first, consisting of seven chapters, deals with "Differential diagnosis of symptoms and signs", and starts with the important subject of pain in the extremities. The various techniques used in studying the peripheral circulation, both arterial and venous, are then described in full. The section ends with a detailed account of the differential diagnosis of physical findings.

The second section is entitled "Peripheral vascular diseases" and forms the main bulk of the book. The final section gives an account of the relevant anatomy, physiology, pharmacology, and pathology. A useful appendix gives the nature of the proprietary drugs and instruments mentioned in the text.

The writing is clear and easy to read. This is a most useful book. The eighteen tables are particularly helpful; they are carefully constructed and are set out in such a way as to be very easy to use. The illustrations are mostly well-reproduced photographs. At the end of each chapter there is a list of references, many to papers written in English; however, it is surprising not to find Martorell's name mentioned. There is a marked medical bias, which is a good thing; surgical details would be out of place in a book of this type. The only important omissions are atrophie blanche and œdème bleu.

The weakest chapter is the one on "rare" vascular disorders. It is surprising to find erythema nodosum included under this heading. The section on stasis dermatitis is poor; no reference is made to the relation between the primary changes in that condition and in the other forms of capillarosis. There are a few minor inaccuracies such as the statement

that the non-tuberculous type of erythema induratum has been described in "recent years". Surely it is unwise to give treatment in bed precedence over ambulatory treatment for leg ulcers.

This is a beautifully produced book with a good index. The adverse criticisms are mostly of a minor nature. It is warmly recommended as a work of reference for practitioners and it will be of much use and interest to physicians and dermatologists. It is not intended for those who specialize in vascular diseases.

A Pictorial History of Medicine. By Otto L. Bettmann, Ph.D. (Pp. xiii + 318; illustrated. 72s.) Oxford: Blackwell Scientific Publications. Springfield, Ill.: Charles C. Thomas. 1956.

Of the making of medical history books and of medical historians who repeat one another, there is no end. Some histories consist almost entirely of names and dates and are useful only for reference; some are too erudite to appeal to the palate of the medical practitioner; others sacrifice accuracy to popularity. Dr. Bettmann's book is refreshingly different, being a snappy commentary on some 1,000 illustrations which tell their own story eloquently and graphically. The history behind this history is an interesting one, for it started with a cigar box. Toying with the idea of writing a pictorial history of civilization, Otto L. Bettmann, Ph.D., Curator of Rare Books at the Berlin State Art Library before the Second World War, began taking photographs of various details in famous paintings, such as food implements, costumes, operations, beards, spectacles, &c., &c. These were filed in a cigar box. With the help of books and documents he then compiled a card index listing his findings. In 1935 he transferred himself and his collections to New York City where he founded the *Bettmann Archive*—a unique collection which supplies historical prints on every conceivable subject to editors, writers, libraries, museums, business houses, and advertising agencies.

"A Pictorial History of Medicine", which starts with Egypt and the Ancient East and ends with Ehrlich, Behring, and Roux, is described as "a graphic record of the untiring efforts of the medical profession to cure the sick, offer solace, allay pain and secure a better life for all mankind". Essentially a non-technical survey, it is intended for the lay public who will find it absorbing and stimulating reading. But it can also be warmly recommended to the medical student, the practitioner, and the nurse who, no matter how pressed they may be for time, will enjoy the wealth of illustrations (many are rare, some are quaint, most are excellently reproduced, and a few are sadly disappointing), the economic, but breezy narrative, and the striking headings which whet the appetite. In a popular work the emphasis is necessarily different from that of a textbook, but on the whole the story of the healing art is well and accurately told. The author has read both widely and wisely, and he carries his learning lightly and unostentatiously. We are glad to find that, though there is a picture showing the Countess of Cinchon "receiving mythical dose of fever-bark tree", the accompanying text makes it quite clear that there is no foundation for this legend. Unfortunately, the drawing depicting Harvey at the battle of Edgehill, 1642, is not similarly "debunked". Proof-reading has been carefully done, though Halsted has an unnecessary "a" on page 301. "This is no 'pictorial souvenir' for the physician to inspect casually and then consign to the patients' waiting room", writes Dr. Philip S. Hench of the Mayo Clinic in his foreword. "Instead it should become a permanent member of his small, desk-side privy council." Dr. Bettmann concludes his book as the twentieth century begins, and we share Dr. Hench's hope "that this is not an end, but a pause, and that a companion volume will tell the fabulous story of medicine's last 50 years".

Symposium of Tuberculosis. Edited by F. R. G. Heaf, M.A., M.D., F.R.C.P. (Pp. xvi + 755; illustrated. 5 gns.) London: Cassell & Co. Ltd. 1957.

There have been a number of books on tuberculosis of recent years in addition to books on diseases of the chest which include tuberculosis, and it may be questioned whether this further addition to the literature is really necessary. Advances in this subject are so rapid that often by the time a book is published it may be out of date. Indeed, Professor Heaf in his introduction recognizes that "the time lag between the correction of the proofs and the final publication unavoidably means that reports are issued and new work is published, which unfortunately cannot be included in this work". Professor Heaf has, however, edited a comprehensive work on tuberculosis from every angle. He has rightly stressed the importance of the preventive aspects and other recognized experts have dealt comprehensively with the epidemiological, pathological, clinical, industrial and rehabilitation aspects as they affect the respiratory and non-respiratory tuberculous subject.

Moreover, childhood and adult tuberculosis is considered and the important aspect of "Tuberculosis in the Tropics" is not neglected. The book should have a wide appeal, especially in backward countries, where public health measures are less advanced.

A few minor criticisms can be made. A number of the illustrations are of poor quality and have not reproduced well. On the clinical side there are some who will question the amount of space allotted to collapse therapy, especially artificial pneumothorax in respiratory tuberculosis which, rightly or wrongly, with the introduction of antibiotic therapy is now very much on the decline. The high price of the book does not altogether seem justified.

Pulmonary Emphysema.—Edited by Alvan L. Barach, M.D., and Hylan A. Bickerman, M.D. 18 other contributors. (Pp. x + 545; illustrated. 80s.) Baltimore: Williams and Wilkins. London: Baillière, Tindall and Cox. 1956.

The subject of pulmonary emphysema is of great clinical significance and, in association with chronic bronchitis, is certainly responsible for much morbidity and mortality in Great Britain. The present volume, edited by Professor A. L. Barach and Dr. H. A. Bickerman of the Presbyterian Hospital, New York, contains contributions by men of international reputation who have done much original research in the field of applied physiology, pathology and therapeutics.

It is recognized that the functional pathology of the bronchi and lung parenchyma in emphysema can, with correct procedures to restore cardio-respiratory function, at times become reversible. These procedures, which must be used discriminately, include oxygen inhalation, antibiotic and steroid therapy, intermittent pressure breathing, chest remedial exercises, the use of broncho-dilator drugs (including aerosol therapy) and adequate bronchial drainage, &c. Continuous inhalation of oxygen is regarded as a valuable agent in the treatment of pulmonary emphysema, especially in the presence of acute hypoxia. The practical application, by many of the contributors, of their researches on respiratory physiology to the realm of therapeutics is noteworthy.

With multiple contributors a certain amount of overlapping appears inevitable and there are also some omissions. There is only one chapter dealing with the significance of infection —a considerable problem in this country. Although the pattern of diseases in the U.S.A. is probably different and chronic bronchitis is probably of less significance than here, one feels the subject might have been discussed more fully.

The book will, however, appeal to all physicians and particularly to those whose interests are directed to the important sphere of cardio-pulmonary disease.

Price's Textbook of the Practice of Medicine. Edited by Donald Hunter, M.D., F.R.C.P. 9th edit. (Pp. xiv + 1774. 63s.) Oxford University Press. London: Cumberlege. 1956.

Dr. Donald Hunter and his collaborators, and especially his publishers, are to be warmly congratulated on this new edition of "Price". A great deal of new material has been incorporated and the book is now indeed a "unique compilation of modern knowledge", eminently suitable to be put into the hands of those at the beginning of a career in any department of medicine in any part of the world. Valuable essays on normal function and on laboratory, radiological and other investigations introduce many of the descriptions of clinical entities. Some further exposition of the erythrocyte sedimentation rate, now so much used, and referred to here and there by various contributors, might profitably be added. It is a question, too, in a textbook of this calibre, whether more space should not be given to diseases of the eye. Glaucoma, for instance, is mentioned only as a complication of epidemic dropsy; and, in another section, it is surprising to find that carcinoma of the larynx is not mentioned at all.

The whole book is extremely readable, and the index is so good that the temptation to look for Tapanuli fever has to be firmly resisted!

A Companion in Surgical Studies. By Ian Aird, Ch.M., F.R.C.S. 2nd edit. (Pp. xii + 1302; illustrated. 84s.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

The outstanding reaction on reading the second edition of this work is admiration for the industry and scholarship of the author. The statement in the preface that there have been added "some thousands of references and nearly 2,000 of them to papers which have appeared since 1950" is an expression of this industry, which few if any potential authors of surgical textbooks in this country could emulate. Of interest, too, in this edition is the copying of the technique of textbook writing introduced in the United States a few years ago, whereby the

work is by a single author but with a consulting editorial committee behind him. The book is an excellent guide to surgical literature, particularly the more recent literature, but there is also frequent evidence of the historical scholarship of the author. The book apparently had its first origins in a collection of post-graduate lecture notes, presumably for final fellowship candidates. The acquisition of a large number of facts and opinions, and the ability to sift and balance them and come to a reasonable conclusion are still a part of the technique of success in the final fellowship, and it is probable that it is by fellowship candidates that this book will be most used. There is, however, a danger that an almost excessive balancing of literary references may train a candidate for something equivalent to a mediæval disputation, rather than educate him in surgery. This danger may perhaps be illustrated in the present work by the discussion of the almost mystical concept of "chronic mastitis". There is also a danger of arguments being put up only to be shot down. But the book must be judged not merely by the place it is likely to occupy in the affections of final fellowship candidates, but as an encyclopædic work of reference. The author's strong historical sense is demonstrated in the way he has tracked down the early references to many of the conditions he describes, e.g. the origins of blood transfusion; the pointing out that what is now generally known as Frey's syndrome was first described by Parkes Weber in 1898; and the reference to the first recorded case of spontaneous rupture of the œsophagus in 1724, occurring in a gluttonous Grand Admiral of the Dutch Fleet. One is surprised, however, that though Cutler's early work on mitral stenosis is mentioned, there is no reference to the much more important pioneer work of Souttar, from which the modern surgery of mitral stenosis in fact stems. It is obviously impossible to review a work of this character in detail, and any reviewer is bound to differ on some points from any author. But surely the statement that "in this country nodular goitre never seems to develop malignancy" is not true. Again, the standard treatment advocated for mixed parotid tumours is the theoretically admirable excision of the tumour together with its false capsule of compressed parotid tissue. But anyone with experience of parotid surgery knows that this is a quite impracticable procedure without routine preliminary identification of the facial nerve and its branches, when the operation becomes in fact the modern conservative parotidectomy. The recorded mortality for excision of the internal mammary chain in operations for carcinoma of the breast is nearer 0% than the "over 10%" of the author. And many surgeons would to-day reject the dogmatic advice that in the treatment of pilonidal sinus "skin and subcutaneous tissue must be excised *en bloc* down to bone over the whole area of suppuration", on the grounds of its being unnecessary and of the long delay in healing so often resulting from this procedure. But in spite of detailed criticisms such as these—which it would be unfair to stress except that they make one wonder how much the consulting editorial committee has in fact functioned—the abiding impression that this book has on the reader is one of amazed admiration for the author's industry and scholarship.

Outline of Fractures Including Joint Injuries. By John Crawford Adams, M.D.Lond., F.R.C.S. Eng. (Pp. vii + 248; illustrated. 27s. 6d.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

This is a simple, dogmatic, but reasoned account of fractures and their treatment, which can be accepted as representing the highest level of present-day practice. The work is designed for the medical student, the general practitioner and the physiotherapist, and starts from the premise that, since fractures are now treated for the most part in special clinics, the details of their treatment are for the specialist, as in the case of other surgical operations. The reader for whom this work is designed need only know the clinical evidence on which "he would suspect and recognize a fracture" and "the general principles of fracture treatment". This is a perfectly sound and legitimate philosophy with the provisos that it needs to be accepted also by examiners in final examinations, and that it is sound only under conditions such as obtain in this country at the present time. The main weakness in the acceptance of the philosophy in its entirety is the argument that, since medicine is in large part a practical art, the medical student who qualifies without himself being able to carry out such simple standard practical procedures as the efficient strapping of the chest for fractured rib, the reduction of a dislocated shoulder, or even the detailed management of a Colles' fracture, is not properly educated. The main question that arises is whether the author has lived up to his philosophy, and in general the answer is that he has, but with certain reservations. Thus, if it is general principles that matter, is the table of 30 causes of pathological fracture on page 14 necessary; or the drawings on pages 214 and 215 of the 14 different varieties of fracture around the ankle joint? The author has added to the interest of the book by brief historical footnotes on some of the chief names associated with fractures, but makes no mention of the key contribution of Böhler in the modern treatment of fracture. But these comments should not be allowed to obscure the fact that this is an excellent book.

DISCUSSION ON ANKYLOSING SPONDYLITIS

Mr. H. Jackson Burrows: Ankylosing spondylitis is a disease of unknown cause, of wide geographical distribution probably not identical with that of rheumatoid arthritis, and characteristically affects young men. It is a general disease with local manifestations, almost always first apparent radiologically in the sacro-iliac joints, and seeming to extend centrifugally to the lumbo-thoracic spine and costo-vertebral joints, the hips and sometimes the knees, and the neck and sometimes the shoulders; and seldom more peripherally. The very variable course tends towards arrest, which is possibly never complete. It is surprising that so distinctive a disease was not generally recognized sooner.

In a patient with the usual complaint of lumbar, gluteal or sometimes root pain and with a stiff back, sacro-iliac signs are rare, but three aids are useful:—a clinical sign: poor chest expansion; a radiological sign: sacro-iliac arthritis; and a pathological sign: raised erythrocyte sedimentation rate. Unfortunately, in the really early case these aids may be equivocal.

In radiological interpretation, the difficulty of distinguishing from other forms of arthritis, notably tuberculous, is well known. Two other particular difficulties arise. The more important is discrimination from the normal adolescent sacro-iliac joint, with its fluffy appearance but invariably intact joint space. The other source of difficulty is osteitis condensans ilii; but this always, or nearly always, affects women, the sclerosis is usually confined to the iliac side of the joint, and the joint space is preserved. In determining these points, oblique films in the planes of the sacro-iliac joints are invaluable.

The erythrocyte sedimentation rate, commonly but not invariably elevated, seldom settles—however seemingly quiescent the disease, which I think seldom, if ever, becomes quite extinct. The test, together with the patient's usual spareness and optimism, points to a general disease.

Less typical manifestations, well described by Golding (1936), are important because they may long precede the rest. Plantar fibrositis, with pain and tenderness at the posterior attachment of the plantar fascia, worse on rising, is sometimes the earliest indication, as in two young surgeons who first complained of painful heels in the operation theatre. Unexplained monarticular arthritis, in a young man's knee for instance, calls for radiography of the sacro-iliac joints. Similarly, iritis is sometimes a very early manifestation. Urethral discharge must be distinguished from that of gonorrhœa or of Reiter's syndrome. Differential diagnosis may require consideration of many spinal diseases: mechanical, degenerative, metabolic, infective and even neoplastic.

Deep X-ray treatment remains the chief standby. Cortisone and its kin are even more effective, but are ill-suited to a disease characterized by osteoporosis, often tuberculosis and often peptic ulceration. Their great use is for the frequent, complicating iritis. The value of exercises, especially breathing exercises, has long been recognized, but their exploitation has often been prevented by pain and spasm in the past before the advent of X-ray treatment brought these under control. Gravity-free exercises in pool or slings are particularly useful, and heat makes exercises easier and more effective. Adequate rest is a corollary of exercise, but does not imply fixation. Occasionally, still, a plaster bed at night is useful, but the patient must first be accustomed to it in hospital.

Although the patient should be encouraged to carry out all the activities within his remaining powers—and he seldom needs encouragement—it must be remembered that stiff joints and fragile bones predispose him to fractures, and that fracture of his spine will very likely cause paraplegia or tetraplegia.

Ankylosis of the lumbar and thoracic spine in good position implies little disability, but if the cervical spine or the hips are also fixed, the disability is great; if the knees also are fixed, the disability is very great indeed, especially if ankylosis is allowed to take place in the "anatomical" position, so that the patient cannot sit. Enthusiasm for the prevention of deformity is sometimes misdirected.

There is not a wide scope for surgery in ankylosing spondylitis. Mobilization of the ankylosed hip may be important. Formal arthroplasty is doomed to failure, but movement can often be obtained by excising the neck of the femur. The consequent instability of the hip can be diminished by a supplementary abduction osteotomy of the femur. The combined operation (resection-osteotomy) has been popularized by J. S. Batchelor. Whether accompanied by osteotomy or not, excision produces movement at the expense of stability, so that the patient has either to bend sideways to bring his centre of gravity over the hip at every step or use a stick; the patient with ankylosing spondylitis cannot bend his trunk sideways, and so is wholly and permanently dependent upon a stick after this operation.

Of osteotomies for ankylosis in bad position, osteotomy (or rather osteotomy-osteoclasis) of the spine is nowadays popular. It should be approached with great caution, because some patients have better function with than without their kyphosis, there is a real danger of paraplegia, and sometimes recurrence is inevitable.

I should like to conclude by acknowledging the great contributions made by radiologists to the understanding and treatment of this disease, and particularly my own indebtedness to Dr. F. Campbell Golding and Dr. Edward A. Allen of the Institute of Orthopædics and Royal National Orthopædic Hospital.

Dr. J. W. Stewart:

The Effect on the Bone-marrow of the Treatment of Ankylosing Spondylitis with Deep X-rays

The development of leukæmia in patients with ankylosing spondylitis treated with deep X-rays (Court Brown and Abbatt, 1955) focused attention on the bone-marrow. This report is based on an investigation of bone-marrow from cases of ankylosing spondylitis undergoing radiotherapy in the Meyerstein Institute of Radiotherapy of the Middlesex Hospital.

There have been very few reports in the literature on the effects of deep X-rays on the bone marrow of living patients—occasional cases only having been reported by Nordenson (1935), Schulten (1937), Meller *et al.* (1938) and Leitner (1941). Denstad (1943), in an excellent paper, surveyed the previous work and reported many detailed results of his own investigations into the subject. Included among his cases are four patients suffering from ankylosing spondylitis. Hutaff and Belding (1955) reported the results of marrow examinations from ilium and sternum in 10 patients with carcinoma of the cervix undergoing treatment with deep X-rays and radium.

METHODS

Bone marrow specimens were obtained by the following methods: (1) Puncture with a Salah needle. This method was confined to the sternal marrow. The site chosen was usually the manubrium but in a few cases the first or second piece of the sternal body.

(2) A small trephine using a Turkel and Bethell needle. The instrument used was manufactured by Messrs. Down Bros., and the large size was always used. This gives a small piece of bone about $\frac{1}{8}$ in. in diameter and about $\frac{1}{4}$ in. long. After removal of the trephine a syringe and adapter were attached and 0·25 to 0·50 c.c. of marrow was aspirated, as when a Salah needle was used. Smears were invariably made at the bedside directly from material in the syringe. 300–500 cells were counted on each smear. The remaining aspirate was placed in an oxalate tube for total cell count. This instrument was used on the manubrium sterni in a few patients and in all patients in whom iliac marrow was examined. The site chosen was just lateral to the posterior superior iliac spine. This is a readily accessible

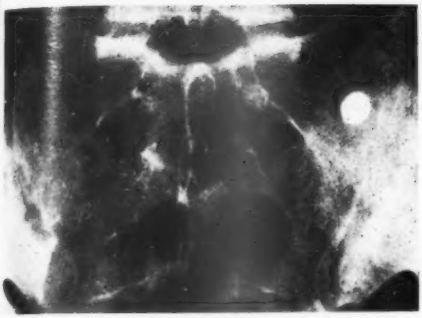

FIG. 1.—Area irradiated in treatment of sacro-iliac joints. Marker shows site of examination of iliac marrow.

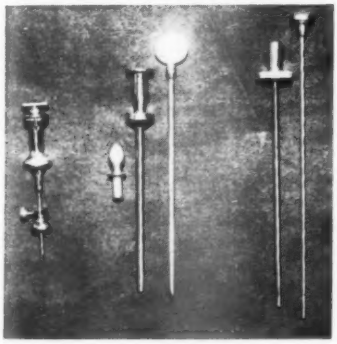

FIG. 2.—Needles used for obtaining the bone-marrow specimens. The small needle on the left is the Salah needle used for the sternal marrow specimens. The remaining instruments are the parts of the Turkel and Bethell needle.

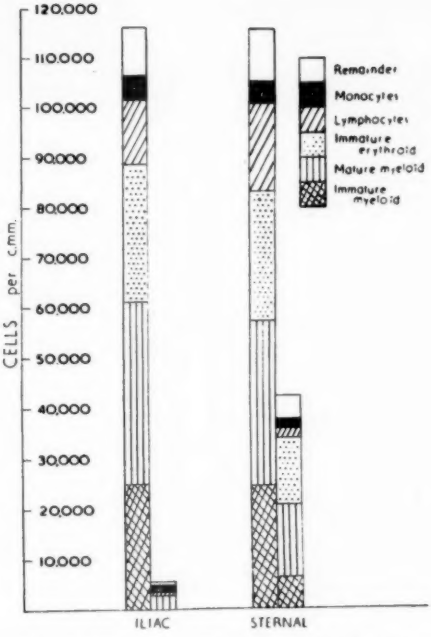

FIG. 3.—Histogram illustrating the effect of deep X-ray therapy on sternal and iliac bone marrows from Case I. In each case the left-hand column represents the result of examination before treatment.

portion of the ilium, the muscle covering being thin and the bone thick, and satisfactory specimens easily obtained. This site is also well inside the treatment area in those cases in which the sacro-iliac joints were irradiated (Fig. 1).

Fig. 2 is a photograph of the instruments used.

MATERIAL

Observations were made on 76 patients attending the Meyerstein Institute of Radiotherapy. Treatment was given with X-rays generated at 200–250 kV. of quality represented by a half-value layer of 0·8–1·3 mm. Cu, at a focal skin distance of 40 cm. A skin dose of 2,100 r–1,900 r was normally attained in fields directed to the spine and sacro-iliac joints. In one patient, iliac and sternal marrow specimens were taken simultaneously with the Turkel and Bethell needle before treatment and seven days after it had finished. This is a representative case and I propose to examine the result in detail.

Fig. 3 is a histogram showing the results of the iliac and sternal marrow examinations from this patient. The left-hand column of each pair is the pre-treatment specimen. There is no significant difference between iliac and sternal marrow before treatment. In each case cellularity is higher than normal but otherwise the marrow is within normal limits.

Seven days after treatment the iliac marrow specimen indicates complete aplasia. The cellularity is very low and no immature erythrocyte or granulocyte remains of the marrow cells, only polymorphs, lymphocytes, monocytes and reticulum cell remain although in greatly reduced numbers. The number of monocytes and reticulum cells are least reduced and so there is a relative preponderance of these types in the marrow count.

The sternal marrow specimen also taken seven days after the end of treatment shows

reduction in cellularity to a normal level. All types of mature and immature bone marrow cells are present but there is some reduction in the number of immature myeloid cells. The immature erythroid cells are relatively less affected and now constitute 31% of the cells present whereas the normal proportion is less than 25%.

Fig. 4 shows the results of iliac marrow examinations before and after treatment in some

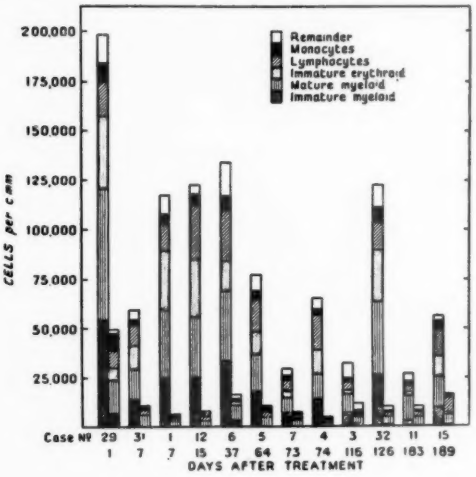

FIG. 4.—Effect of deep X-ray therapy on bone marrow included in treatment area. In each case the left-hand column represents the result of examination before treatment. [(1956), *Lancet*, ii, 1063. By kind permission.]

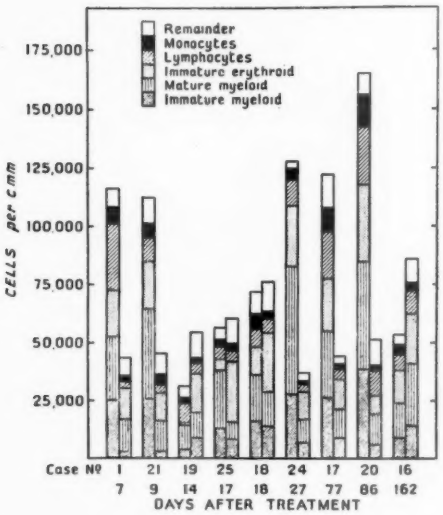

FIG. 5.—Effect of deep X-ray therapy on bone-marrow distant from treatment area. In each case the left-hand column represents the result of examination before treatment. [(1956), *Lancet*, ii, 1063. By kind permission.]

other cases undergoing deep X-ray therapy. Again, the left-hand column of each pair represents the pre-treatment specimen. The post-treatment sample has been taken at intervals of between one day and six months after the finishing of treatment. It can be seen that from about one week after the end of treatment until at least two months later the bone-marrows are aplastic and no immature myeloid or erythroid cells are present. After this time a very few immature cells make their appearance but even six months later the marrows show a very severe hypoplasia.

Fig. 5 is a histogram of the results of sternal marrow examinations in patients being treated with X-rays for ankylosing spondylitis. This site was chosen as it is convenient and at the

same time not directly within a treatment area. The left-hand column of each pair represents the pre-treatment specimen and once again punctures are done at varying intervals in each case from one to twenty-three weeks after the end of treatment. The response of the marrow distant to the site of treatment appears to fall into two types. In the first category represented by these patients who had hypercellular marrows before treatment (Cases 1, 21, 24, 17 and 20 in Fig. 5) the immediate result was a reduction in cellularity to normal levels. In each case the reduction was most marked in the case of the immature myeloid cells, although absolute numbers of all cell types were reduced. In the second category, represented by these patients in whom the marrow cellularity was within normal limits at the commencement of X-ray therapy (Cases 19, 25, 18 and 16 in Fig. 5) there was little alteration in cellularity after treatment, but there was a change in the myeloid/erythroid ratio especially during the first six to eight weeks following the cessation of treatment by X-rays. These cases all showed an erythroid hyperplasia associated with a mild degree of myeloid hypoplasia.

Denstad (1943) and Hutaff and Belding (1955) observed a similar erythroid hyperplasia in marrow distant to site of treatment. This finding is difficult to interpret. The most obvious explanation is that hyperplasia is compensatory as the iliac bone-marrow is aplastic at this period. But this cannot be the full explanation as the iliac marrow is still aplastic after the sternal marrow has returned to normal limits. It may be that hyperplasia is temporary compensation until a redistribution of hæmopoietic activity has occurred and that normal inactive marrow, e.g. in the femoral shafts, has resumed hæmopoietic activity to replace marrow rendered aplastic in ilium and spine by the deep X-ray therapy. This has not yet been proved but might gain some support from the results of the peripheral blood counts, since all cases of ankylosing spondylitis under treatment show no significant alteration in hæmoglobin concentration but a marked leucopenia, particularly neutropenia, which has largely recovered by the end of the second month after therapy has ceased.

The use of the Turkel and Bethell needle enables a small bone and bone-marrow biopsy to be taken and a section of such a specimen is shown in Fig. 6. This is from the iliac bone

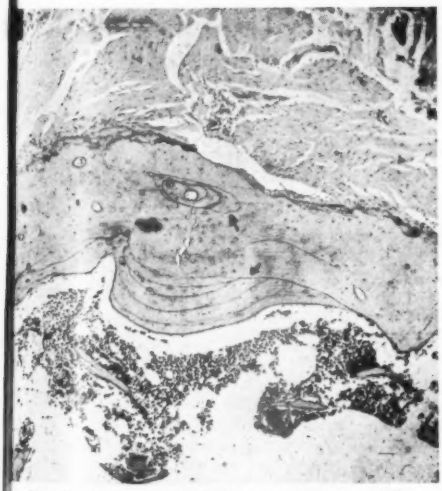

FIG. 6.—Iliac marrow before treatment. ×75.

FIG. 7.—Iliac marrow from Case 1 after treatment. ×75.

of Case 1 discussed previously. The periosteum and bone are normal and there are cement lines (arrowed in Fig. 6) indicating that bone has been recently laid down. The marrow is more cellular than normal but is otherwise unremarkable. Fig. 7 shows a similar specimen removed from the opposite ilium seven days after deep X-ray therapy has ceased. The periosteum is somewhat acellular and the bone looks normal and lacunæ contain bone cells. But cement lines are completely absent. This has been noted in many post-treatment specimens in these patients. The bone-marrow is aplastic—only a few polymorphs, monocytes, lymphocytes, reticulum cells, occasional plasma cells and fatty tissue remain.

This is an invariable finding in these patients receiving 2,000 r or over. Fig. 8 and are high-power views of the pre-treatment and post-treatment marrow specimens respect ely.

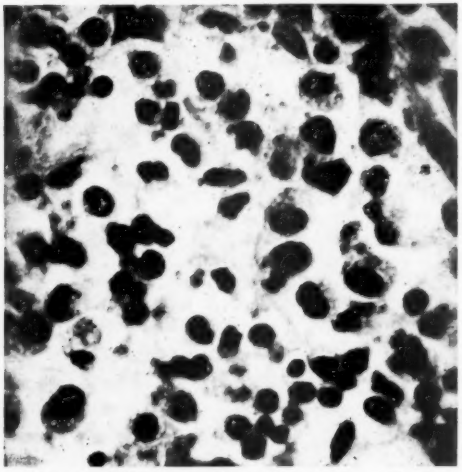

FIG. 8.—High power view of iliac marrow from Case 1 before treatment. ×565.

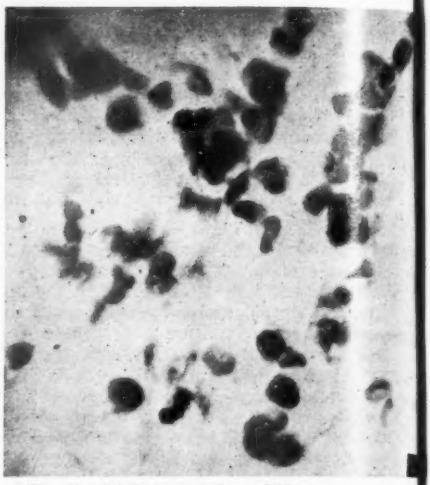

FIG. 9.—High power view of iliac marrow from Case 1 after treatment. ×565.

A special search was made into the bone-marrow smears for abnormal cells. Before treatment osteoblasts were present in large numbers in a sternal marrow smear from a patient who had no symptoms referable to the sternum. This is a most unusual finding especially in adult marrow specimens. Osteoclasts were occasionally seen. In post-treatment marrow specimens from a treatment area giant polymorphs were occasionally seen. Monocytes with vacuolated cytoplasm and nuclei were a very common finding. These are not specific or unique to deep X-ray treatment but they are encountered much more frequently in the marrows of patients who have such therapy. Mitotic figures are virtually non-existent, but as the time after the cessation of the deep X-ray therapy increases, they can be found in slowly increasing numbers.

I wish to thank Professor B. W. Windeyer and Miss M. D. Snelling for allowing me access to their cases and to Dr. S. Dische for his help and co-operation.

DISCUSSION ON FACIAL AND PALATAL REPAIR IN THE TREATMENT OF MALIGNANT DISEASE

Mr. W. A. Mill: Malignant disease of various types may affect the different tissues and structures making up the face and mouth. In the majority of cases treatment in the first place is by radiotherapy. Sometimes no further treatment is needed but only too often surgical excision has to be undertaken. Not surprisingly in a number of cases gross deformity results. This is an outline of the corrective procedures that are undertaken to restore function and comfort to the patient. It is desirable that the patient should continue to live as normal a life as is possible and that he should not be afraid of meeting his fellows. His appearance therefore must be made as good as it reasonably can be. Repair may be necessary following treatment of growths involving the upper or lower jaws, the cheek, the lips, and the palate; growths of the nose may extend to the cheek and to the orbit and ethmoid or even the upper jaw and this is notoriously so of basal cell carcinomata.

Many of the patients are old and they have had treatment of various kinds extending over many years and quite often there have, in the past, been a number of operations to deal with repeated recurrences. In many cases previous radiotherapy has made the tissues rather devitalized so that healing may be difficult if a further operation is undertaken. Many patients, particularly the old, are most unwilling to have further operations. In deciding what repair is to be done it is necessary to keep these points in mind.

Excision, if it is undertaken, must be adequate. Before operation multiple biopsies will have shown the extent of the malignant disease and at the time of operation use should be made of the frozen section technique to ensure that removal of the growth is complete. With basal cell carcinomata some recurrences are certainly true recurrences but in some cases one seems to be dealing with multiple new foci. Although involvement of lymph glands is exceptional with rodent ulcers the neoplastic cells may invade the skin lymphatics and secondary nodules may be seen near the main lesion.

Immediate repair.—A certain amount may be done at the time of operation to minimize deformity and to accelerate healing. Where it is possible Thiersch grafts should be applied so that rapid epithelialization and the prevention of scar tissue formation may result. When it can be done the sewing of mucosa to the skin has a similar effect. This is important to keep the tissues in as good condition as possible with the minimum of scarring, especially if subsequent plastic operations are to be undertaken.

In some cases partial or complete repair can be done by transposed skin flaps, particularly about the ear.

Of course a good window must be left to make sure that any recurrence will be noticed and for this reason the covering of cavities should not, as a rule, be done at the time of the operation of excision.

Palate.—If it is intended to remove part of the hard palate, a prosthesis should be made before operation so that it can be worn after operation, perhaps the following day, or a day or two later. This adds to the comfort of the patient. Later, of course, when healing has occurred a permanent obturator is made. These are as a rule satisfactory even in the edentulous but if there are teeth in the opposite maxilla fixation is of course easier to obtain. Occasionally the palate may be repaired by plastic surgery by sewing the margin of a re-formed cheek on to the palatal edge.

Later repair.—It must be emphasized that it is usually wise to wait for a long period before undertaking any major plastic reconstruction. It is essential to ensure the absence of the recurrence of disease and as a rule only the passage of time will give this certainty. During the period before operation a temporary prosthesis is a great help and comfort.

In the young, if it is at all possible, plastic procedures should be carried out. In the old however, the correction, or perhaps one should say covering, of the deformity can well be done by fitting a prosthesis. This is usually of acrylic resin but sometimes it is made of metal. The prosthetic appliance is tinted to match the patient's colouring and usually very good results are achieved. The colours of the prosthesis do fade in time and the appliance gets dirty and so renovation is necessary at intervals.

Growths of the antrum and palate.—In many cases a very long sublabial incision passing well to the healthy side is all that is required in removal of the palate or partial removal of the upper jaw. The whole maxilla can easily be removed through such an incision. The only repair needed is an obturator to close the opening in the palate.

It is sometimes necessary to make an incision in the face by the side of the nose with division of the upper lip and this will give a better exposure. At times extension of the incision laterally through the lower conjunctiva may be required and this incision may be prolonged outwards from the external canthus in some cases. These incisions heal with little scarring. Any incision across the side of the face below the eye is likely to result in persistent œdema of the lower eyelid.

Sometimes the skin of the cheek is invaded by growth and must be excised. A gap in the cheek may have to be left. Where possible mucosa and skin should be sewn together or possibly Thiersch grafts applied. If the gap is not too large it may be closed by suturing at the time of the operation. If a gap remains later plastic operation may be necessary. In some patients, however, a prosthetic appliance answers very well. On the whole in younger patients it is best to try to obtain a covering of natural tissues by plastic operation.

Sometimes after operation on the upper jaw there is scarring with raising of the corner of the mouth which may be corrected by a relatively minor plastic operation (epithelial inlay). At other times subsequent necrosis of bone, particularly of the malar bone, may produce unpleasant deformity which a plastic operation could correct.

Usually the eye does not drop even if the orbital floor, that is the antral roof, is removed, but it may do so if the removal of bone has to be carried high on the inner and outer sides of the orbit. However in my experience the resulting diplopia is not as a rule persistent. No dental obturator will hold up such a fallen eye.

After removal of the maxilla mucosa readily covers the raw area. Some surgeons skin-graft the walls of the cavity but this does not seem to be necessary.

Nose.—When the nose has to be removed repair may be by plastic operation or by prosthesis. In the young there is a strong place for plastic reconstruction but in the older patient a plastic nose is very satisfactory.

Orbit and ethmoid.—If the orbit has to be exenterated the skin of the eyelids should, if possible, be preserved to give a partial lining to the cavity and the rest may be covered by Thiersch grafts. If the orbit alone has been exenterated or the orbit and ethmoid, many patients prefer to wear an eye patch—an eye patch is so often worn that the appearance is not unusual. A plastic prosthesis with an artificial eye looks well in photographs but the eye does not move and looks unnatural. Many patients prefer a plain skin-tinted prosthesis worn with a patch or an opaque spectacle lens. It is certainly not advisable to cover the orbital opening with a skin flap—it is still unsightly and has to be hidden from view in some way.

FIG. 1 (1950).—Epithelioma of nose and eyelid following lupus.

FIG. 2 (1951).—Result of excision. (W. A. M.)

FIG. 3 (1956).—Patient wearing prosthesis.

Cheek and lower alveolus.—Growths involving the lower jaw are largely outside the scope of this discussion. The problem of repair may well involve a temporary prosthesis for some time and subsequently plastic procedures and even bone grafting. The same considerations apply to growths of the cheek which often involve the lower jaw and sometimes the upper jaw.

Ear.—The ear is a most difficult structure to build adequately by plastic surgery. The prosthetic ear is most satisfactory and it is the general method of repair used. At the time of operation a good deal of immediate repair may be done by Thiersch grafting and the arranging of transposed flaps. It is important to graft the external auditory meatus at its entrance, to avoid stenosis.

It will be seen that the aim is to obtain good function for the patient and at the same time a reasonable appearance. It is important in the old, who have suffered a great deal in the past, to remember that too many operations have spoilt their lives. Much may be done to help them with prosthetic appliances.

I wish to thank Mr. R. J. V. Battle for his co-operation in the treatment of many of the cases and also Mr. J. H. Hovell, who has undertaken the making of palatal prostheses. I must also thank Mr. F. R. Coffin of the Royal Marsden Hospital, who has made the palatal prostheses for many of my patients.

Mr. R. J. V. Battle: In facial reconstruction for malignant disease many factors must be considered.

Firstly: There is one golden precept that must always be followed: Once the diagnosis of malignant disease is made there must be no delay in the eradication of this disease by any preliminary preparation of complicated reconstructions. For example there should be no preparation of flaps that might delay treatment.

Secondly: Pathological considerations only should be allowed to dictate treatment. Fortunately the greater number of lesions reaching the surgeon are purely surface lesions and of these the majority are rodent ulcers.

SURFACE LESIONS

(1) *Rodent ulcers.*—Nearly all of these, except those round the eye, have been irradiated and have recurred. Some have been considered too wide and penetrating for irradiation. One group of deeply infiltrating lesions require extensive surgery if they are not to recur locally. Moreover they produce by some trigger action, not fully understood, other primary lesions in the neighbourhood, so that the extent of the primary excision is no guarantee against recurrence.

Very fortunately none of these lesions metastasizes, but in the infiltrating group early reconstruction is contra-indicated, and wherever possible a prosthesis must be considered for the interval during which recurrence might be expected.

(2) *Squamous cell carcinomata.*—These are very much more rare in white skins than are the basal cell lesions. The reaction of these tumours round the lips to irradiation has perhaps explained why reconstruction of the upper and lower lips is so much less in demand than would appear to have been the case in the last century. The devastating spread to glands and occasional dissemination in the blood stream make one feel that early complicated reconstructions are a waste of time, and that the fitting of a prosthesis for a period of at least two years is a more sensible procedure.

(3) *Malignant melanomas.*—With the appalling prognosis extensive reconstruction is out of the question, but may be indicated on two grounds. Firstly where function is grossly disturbed—e.g. with a large defect into the oral cavity—or secondly where there is great disturbance of morale, and it is imperative that the patient should be reassured or rather "kidded" into thinking that the removal of the local lesion means the end of all anxiety.

(4) The rapidly-growing anaplastic tumours may react to irradiation and very few need be considered for serious reconstructive surgery.

DEEP LESIONS

From the point of view of reconstruction these fall into two groups:

(1) Those affecting the antra, the nose and the palate—i.e. the middle third of the face. These can again be subdivided into two groups:

(a) When skin covering is not affected.

(b) When the skin covering must be removed.

Group A.—The chief reconstructive problem falls to the lot of our dental colleague and

is limited to obtaining rapid healing (perhaps with the help of an epithelial inlay), the camouflage of the falling in cheek by the same method, and the restoration of function by the provision of a denture. Where necessary the reconstruction of the palate may be effected by the introduction of skin. This must be transferred from a distance as a tubed pedicle flap by a fairly lengthy and difficult process, and only when the fear of recurrence is minimal and the procedures can be carried out at leisure.

Group B.—The early provision of a skin covering is a debatable problem. There must be a real danger of masking a recurrence by such an early procedure. I have, in my own small experience, seen several patients in whom recurrences deep in the nose have been missed and the patient eventually lost by too early reconstruction. The exact time factor in this problem is difficult to determine. It is possible that an examination of the tissue removed will give the clue. I used to work on a standard time lapse of one year between excision and reconstruction but I doubt if this is long enough. I think that two years may be the better interval of time—the patient getting on with a prosthesis during that period.

(2) Those lesions affecting the tongue, lower jaw and glands of the neck. Briefly, the problem here is that of removing the tumour with its entire lymphatic field as a single tissue mass at one operation. In the more advanced cases very great ingenuity is required in order to obtain a watertight closure of the buccal cavity, and in obtaining an ample supply of viable skin covering from the neck. In these patients no external prosthesis can ever replace the watertight closure of normal tissues, and for practical purposes need never be considered, unless it be in the form of a simple cup in which dressings are contained.

Thirdly: Anatomical considerations.

THE EYE AND THE EAR

The eye and the ear present special problems of their own.

(1) *The eye.*—Destruction of part of one or of both eyelids must at once be followed by reconstruction, or else the eye is lost. With any invasion of the orbit, this has to be exenterated leaving a large raw surface of bone to be covered. It has usually been my practice to employ the forehead for this cover—a somewhat extravagant procedure that has two advantages. Firstly it is an insurance of quick healing with a durable skin cover that will bear the weight of a prosthesis, and secondly this will also stand up if necessary to irradiation of any subsequent recurrences. Against the immediate use of the forehead the orbital bone readily accepts a Thiersch graft and the forehead can be spared for use later, should recurrences lead to a necessity for exposure of the cribriform plate or the dura or the underlying brain itself.

Furthermore no reconstruction can produce anything similar to the normal eye with its movements, and eyelids with their closure, and there is therefore only one ultimate fate for these patients who have had an exenteration—a prosthesis to conceal their deformity from the prying eyes of their fellows. A ground glass in their spectacle frame is not enough. The prosthesis can be a simple eye shade in type that conveys the Nelson touch, or else it can be more complicated and can carry an eye and an eyebrow.

(2) *The ear.*—There is not the same urgency in dealing with the ear that there is with the eye. Small losses may be made good at leisure. Removal of the ear in an adult must be followed by the wearing of a prosthesis. The only indication for total reconstruction of the ear in an adult must be an inability on the part of the patient to tolerate the gadget. If he demands a reconstruction then it must be pointed out that many stages will be necessary and that the final object will in no way resemble an ear!

In the severe cases in which the lateral sinus and dura become exposed, and certainly in those where the temporo-mandibular joint remains open to the four winds, a scalp flap is always available to produce the necessary protection and backing for the subsequent prosthesis.

In all severe lesions involving the eye and the ear our only problem is to obtain early healing with sound skin cover and then to organize a camouflage by artificial means.

Fourthly: Other factors which influence our treatment. These patients are mostly in the older age groups, few are under 50 years of age and many are over 75. Many of them, often out of sheer perversity and in anticipation of the horrors of a surgical operation, have held on to their lesions for long periods of time. These are poor material for reconstruction with its repeated surgery, discomfort and hospitalization. It follows that we often adopt the prosthesis where against a more normal psychological and physical background we would prefer flesh and blood.

Another factor is the effect of irradiation. The presence of a new growth in a field that has been heavily irradiated means at once a multiplication of all the hazards attendant on the transfer of skin flaps, the take of skin grafts and on even the simplest forms of wound suture.

We have come, therefore, to consider reconstruction in this field under two headings:

(1) *The immediate repair.*

(2) *The delayed or "interval" reconstruction.*

(1) *The immediate repair.*—In the immediate repair we are not only concerned with the raw surface left by the wide excision of the lesion—we have to prepare the stage for any subsequent procedures.

If the lesion is superficial and if the pathology is not fully understood, then the immediate application of a free graft is advised. In the smaller lesions the post-auricular Wolfe grafts have become increasingly popular on account of the improved cosmetic result obtained.

A flap is required for the immediate repair under the following conditions:

(i) Deficiencies in the eyelid of full thickness.

(ii) Where cortical bone is exposed (the only exception being the orbit which will take a free graft).

(iii) Where the dura, lateral sinus or temporo-mandibular joint is exposed.

Wherever possible the employment of a local tissue flap should be considered—either as a transposition or as a rotation. If not available then a forehead flap must be brought down.

In large defects in the upper face—e.g. into the buccal cavity, or after amputation of the nose—careful suture must be planned of the marginal skin to the mucous membrane of the lining of the cavity. This is not merely to obtain rapid healing *per primam*, but also to minimize the degree of marginal scarring. We are, in fact, preparing for the later reconstructive phase when it may well prove desirable to turn lining flaps based on this very margin.

Many of the lesions that we see are recurrent lesions where there has been an extensive irradiation of tissues. The failure to appreciate the extent of tissue damage and the inability to replace all such devitalized tissue by reason of its sheer extent are potent reasons for defeat. This applies particularly in the employment of local flaps and in the repair of lesions of the lower third of the face, where a watertight closure is essential in the primary repair.

(2) *Delayed or "interval" reconstruction.*—In the ear and after exenteration of the orbit the employment of a prosthesis can be described as satisfactory only in that it allows the victim to wander unnoticed amongst his fellows. It must, however, be very irritating and depressing to have to "dress up" every time you leave the house, and there is the constant fear that you may lose a vital part of your "make up" every time you run for a bus or look out of a carriage window. Here indeed surgery has proved wanting and further progress must be looked for.

In the nose, however, the cosmetic prosthesis is far less satisfactory—not that it is inferior to most of the noses reconstructed in flesh and blood. The simple fact is that you can blow a reconstructed nose and that you cannot blow an artificial one. Surgeons of many generations have studied this problem. The earliest technique employed is the Indian method, by which the forehead is brought down. This technique gives the best nose, but produces a secondary defect that in the male is better avoided if possible. Then the Italian method, by which the upper arm is employed to provide the flap, gives nice results but entails maintaining the arm in a somewhat fixed position. In the older patients I should say that this method is contra-indicated.

A tubed pedicle raised on the chest is a little difficult to handle but entails a less fixed position and can be brought up to the nose without the use of a vehicle to transport it. The male chest may be too hairy, and in the female any scar on the chest is better avoided except in older patients.

Such a pedicle can be transported from the abdomen on the wrist and brought up to the face. Again in this technique we are up against an agonizing period of immobilization of the arm. The colour match tends to be disappointing.

In all I favour the forehead in most cases but would only adopt any particular method after a full discussion with the patient.

Large defects in the middle third of the face or of the buccal cavity must be closed by the introduction of one or more flaps: all the flaps mentioned—forehead, arm, chest and abdomen—being available. Furthermore the flap introduced for cover must either carry its own lining or else lining flaps must be planned and brought into position simultaneously. It is in the provision of this lining that the greatest ingenuity is required and the various techniques involved can be summarized as follows:

(i) Flap for covering, lined with Thiersch graft. Such a lining is not advised if bone will later be introduced either for contour restoration or to replace missing mandible.

(ii) Local flaps turned over to act as lining—not possible if the area has been heavily irradiated. In all cases they are better not delayed, since they are raised and turned through an angle of 180 degrees and based on scar tissue. These flaps are very vulnerable.

FIG. 2 (March 1950).—After excision and Thiersch grafting. (Operation by W. A. M.)

FIG. 3.—To show method of repair (R. J. V. B.).

(iii) The introduction of one flap (e.g. forehead) for covering another flap (e.g. chest) for lining.

(iv) The insertion of a flap all round the margin of the defect. When this has settled in, a part of it is turned in for lining and the rest spread across for covering.

Finally there are a series of operations by which we can assist the dental prosthetist and in this way improve function:

(*a*) Epithelial inlays.

(*b*) The introduction of tubed pedicle skin to repair the palate.

(*c*) Freeing jaw fragments in order to obtain a better occlusion.

(*d*) The repair of the upper lip—with special emphasis on the Estlander and the Abbé procedures.

(*e*) Finally the closure of the mouth from the rest of the face in those extensive lesions in which the greater part of the face has been removed.

CONCLUSIONS

(1) The pathology of the lesion dictates the reconstructive programme. The possibility of a recurrence being masked by the repair swings the balance towards the use of a temporary prosthesis until the chance of recurrence is minimal.

(2) Severe lesions of the ear and eye are best treated by a prosthesis. Reconstruction has little to offer here as yet.

(3) The age and attitude of the patient will dictate the ultimate degree to which reconstruction will be possible, and may lead to the selection of a prosthesis where normally flesh and blood might have been preferred.

(4) A brief résumé of the procedures available both in immediate and delayed reconstruction is given with examples, the emphasis being on the restoration of function rather than of appearance.

Mr. J. H. Hovell: The dental surgeon is gravely handicapped both in the immediate post-operative period and in the long-term prosthetic management of these cases if he has not had the opportunity of seeing them pre-operatively.

The ideal is personal consultation between surgeon and dental surgeon as soon as operation has been decided upon. The probable extent of the excision, the number of teeth which can be left and the need for post-operative radiotherapy are all of importance if the best possible results are to be achieved.

The next step is to obtain duplicate pre-operative models of the patient's jaws, and, should he be edentulous, also one of dentures. One of these and that of the dentures is kept as a permanent record, the other is used for the construction of the immediate post-operative appliance.

It has been found desirable that an appliance should be constructed before operation for immediate post-operative insertion. This appliance (Fig. 1) performs several functions:

(1) It maintains the pack in position, prevents it from being disturbed by the tongue and minimizes contamination by food.

(2) It is a great aid to speech and deglutition.

This prosthesis which is made in duplicate is constructed to conform to the original shape of the patient's palate and alveolar process. If teeth are present on the unoperated side these are used for retention and a flat biting surface is provided on the other side of the same vertical height as the original teeth.

When the patient's own dentures are available it is unnecessary to construct a duplicate appliance as the former will act perfectly as the first prosthesis and to maintain the pack. A second upper denture is, however, made before operation to act as a base later for the second prosthesis.

The most comfortable pack for use after the removal of the initial post-operative packs has proved to be a small marine sponge, cut, if necessary, to the approximate size and shape of the cavity.

The length of time during which this appliance continues to give service depends greatly upon whether or not post-operative radiotherapy is employed.

Post-operative radiotherapy is a major difficulty for the dental surgeon as it gives rise to a slowly healing cavity which continues to change shape and to sequestrate bits of bone, often for as long as twelve months. During this period frequent adjustments have to be made to the prosthesis in order to maintain the patient in reasonable comfort.

Normally speaking it is a good rule that prior to radiotherapy about the mouth all teeth should be removed, in order to minimize the risk of osteo-radio-necrosis arising subsequent to a later extraction. This danger of radio-necrosis is such that some authorities—Kelsey Fry for example—consider even the wearing of dentures to be dangerous.

This rule, however, is not adhered to when dealing with radiotherapy following surgical extirpation of maxillary neoplasms for the following reasons:

(1) Radio-necrosis is far less likely to occur in the maxilla than in the mandible.

(2) The radiation is localized within the cavity and not "beamed" through the teeth, thereby minimizing remote effects and "scatter" from the teeth.

(3) The retention of teeth is extremely desirable. First they are the greatest possible aid to the retention of a prosthesis. Second they may be needed to support an appliance carrying a tray for an epithelial inlay in a subsequent plastic repair.

(4) They seldom have to be extracted as the strain of helping to support a prosthesis ultimately invariably causes them to be loosened and finally to drop out from a socket lined with granulation tissue from which the bone has completely receded. It has not yet been my experience to see a radio-necrosis arising in the maxilla as a result of a tooth being lost in this way.

It is, of course, necessary to remove the teeth immediately adjacent to the area excised, and the remaining teeth should be carefully watched and conserved so as to eliminate the possibility of abscess formation following carious exposure of the pulp.

Until healing of the cavity is fairly complete and all major sloughs and sequestra have separated, it is undesirable to attempt to obtain an exact impression of the whole cavity. The suction created and the difficulty of removing an exact impression may at this stage give rise to a severe secondary hæmorrhage.

If, therefore, a method of radiotherapy necessitating an exact cavity impression is to be employed, this must be taken at the time of operation before the cavity is packed. This is not done at St. Thomas's where the radiotherapists prefer to irradiate the cavity with one large needle placed centrally in a marine sponge.

The degree of comfort obtained with this first prosthesis and a sponge is such that there is no urgency to replace it with a more accurately fitting appliance and I usually wait for three to four weeks when the cavity is fairly clean and the surgeon gives the "all clear" for the next stage.

The most important factor for the comfort of the patient wearing a prosthesis is the maintenance of a complete peripheral seal to the cavity. Even at this time it is impossible to obtain a total impression but by building up the prosthesis already constructed with soft wax a rough outline of the cavity margins is obtained. An accurate impression of these is then taken with elastic impression material using the prosthesis as a base.

Having obtained the impression the next problem is to obtain maximum retention and stability. Neither at this time nor later when healing is complete can undercuts in the cavity be used as an aid to retention. The inevitable movement that occurs causes rubbing and ulceration of the mucosa if this is attempted. With this prosthesis, therefore, stability must depend upon the elimination or reduction to a minimum of any possible displacing factors.

The first and most important of these is the weight of the appliance. Because of this it is made as light as possible, and no attempt is made to construct a bung going up into the cavity. The second displacing factor is the movement of the teeth and occlusal forces during mastication. To eliminate this the biting surfaces of the teeth are set up on an anatomical articulator designed so that the movements of the jaw are exactly duplicated. In this way cuspal locking is avoided and the bite balanced in all excursions of the mandible.

The third displacing factor is the soft tissues. Normal activity of the oro-facial muscles exerts forces upon the prosthesis. These forces are balanced before removal of teeth between the tongue inside and the muscles of the cheeks outside. This then is the reason for obtaining records of the patient's own teeth or dentures before operation. The dental arch of the prosthesis must be the same as that present before operation in order that this balance of forces should not be disturbed.

In addition to activity there is also the effect upon soft tissue morphology of the surgery. Scarring and contraction of the tissues is frequent with resulting changes in facial contour. It is useless to attempt to correct these changes by the prosthesis, as the tissues will not permit this and instability is the only result. It is occasionally felt essential later that for æsthetic reasons such deformity should be corrected. In such a case an epithelial inlay must be inserted in the region of the scarring to form a pocket into which the prosthesis can be extended without creating a displacing force from the tissues.

Ultimately when healing is complete it is necessary to make a final prosthesis. This may be up to a year from the time of operation, and in the interval adjustments to the original prosthesis are usually necessary. For this reason duplicate prostheses are highly desirable as otherwise the patient has to be without one while this is being done (Figs. 2 and 3).

Unfortunately even when healing is complete it is found that the roof of the cavity is not capable of weight-bearing, and therefore peripheral seal remains the most important factor. It has been found, in fact, that in a large number of cases the extension of a bung into the cavity not only is no aid to stability, but actually, by increasing the weight of the appliance, reduces it.

FIG. 1.—Type of appliance used immediately post-operatively and also frequently as a permanent appliance.

FIG. 2. — Prosthesis with hollow bung extending into cavity.

FIG. 3.—After excision of rodent ulcer with prosthesis showing in cavity. (Operations by R. J. V. B. and W. A. M.)

Attempts have also been made to utilize undercuts by constructing the appliance in two sections inserted separately and united in situ. Not only is the pressure on the undercut not tolerated by the tissues but the additional weight and difficulty of insertion of the appliance are not tolerated by these mostly elderly patients.

In the majority of unilateral cases, therefore, no bung is now used.

Springs between lower and upper dentures can be used to aid stability. When a bilateral removal of maxilla has been undertaken, these are quite satisfactory and in fact usually the only method of obtaining a reasonably stable result. In unilateral cases, however, they are of use only when a pressure-bearing surface is available on the operated side. Otherwise they tend to tilt and displace the appliance instead of maintaining it in position.

Finally, even with ordinary full upper and lower dentures it is frequently impossible to obtain complete comfort with elderly patients wearing them for the first time. Too much must, therefore, not be expected in all these cases from prosthetic replacements.

The President said that in the case of a patient with one of these lesions it was necessary to consider carefully what deformity there would be after an operation for complete removal of the neoplasm.

Mr. E. Musgrave Woodman said that, in his Hunterian Lecture of 1926, he laid emphasis on two important principles in the surgery of this area.

Firstly the fullest exposure possible must be obtained and for this purpose he turned back the face by a paranasal incision commencing above through the eyebrow. Suturing

was by subcuticular silk and a dressing of gold leaf and the resulting scar in a few months was hardly noticeable.

Secondly it was vital to leave a window of inspection so that the operation area could be adequately watched for a recurrence. For this reason he invariably removed the hard palate of the same side and the opening was closed by a dental obturator.

He agreed with Mr. Mill that dislocation of the eyeball could be avoided if the tissues were kept still and fully supported for ten days.

Mr. Mill, in reply, agreed with Mr. Musgrave Woodman that if one wanted to get a really good exposure of the pterygoid region it was advisable to turn back the cheek. He also agreed that if a lateral incision had to be made it was better to make it through the lower conjunctiva and not through the eyelid, because this resulted in œdema. Even if one had to take the roof of the antrum away the eye, as a rule, did not drop and there was no doubt that packing of the cavity afterwards did help to keep the eye up. However, if one had to carry the removal of bone rather higher than usual on the medial and the lateral sides the eye did sometimes drop and he knew no way to prevent this.

Most of the patients he had been discussing had had treatment by radiotherapy before they were operated on. Occasionally with malignant disease of the antrum in older patients excision was carried out first and this was followed by treatment by a radium applicator. There were some old patients who could not face up to a long course of radiotherapy to be followed later by operation and provided the cases were not too extensive they could be treated in this way.

In reply to a question about lymph nodes he said that he did not agree with prophylactic block dissection. He regarded block dissection as causing a certain amount of morbidity in older patients and he thought it was better as a rule to wait until enlarged glands could be felt before advising it.

Before operation biopsies, if necessary multiple, were taken to judge as far as possible the extent of the growth. During operation, especially in cases of extensive rodent ulcers, use was made of the frozen section technique to make as sure as one could that one had excised all the diseased area.

He wished to thank Mr. Warren of Messrs. Clement Clarke and Mr. A. Brook of Queen Mary's Hospital, Roehampton, for their great help with prostheses.

Mr. Battle, also in reply, said with regard to the use of the forehead that one should avoid bringing hair down on to the nose or on to the face. Any hairs introduced in this way could not be removed effectively by irradiation and would have to be removed surgically.

In employing bone grafts for the restoration of contour he used cancellous bone from the ilium. If for any reason bone was contra-indicated, cartilage made a good second best.

Some of the prostheses had been produced by Mr. A. Brook of Roehampton.

A DISCUSSION on **Benign Tumours of the Larynx** was opened by **Mr. F. C. W. Capps** and **Mr. J. P. Stewart; The President, Mr. J. McFarland** and **Mr. S. W. Allinson** also took part in the discussion.

The following clinical records were presented:

Chondroma of the Arytenoid.—Mr. L. F. W. SALMON.

Bilateral Laryngocele (with film).—Mr. G. H. BATEMAN and Mr. J. KODICEK.

Non-Specific Granuloma of Larynx.—Mr. R. SALKELD.

Primary Carcinoma Presenting in Right Nostril—Maxillary Resection with Osteoplastic Restoration of Antrum.—Mr. W. O. LODGE.

Tuberculosis of the Pharynx (Two Cases).—Mr. P. E. ROLAND.

Cerebrospinal Rhinorrhœa Associated with Osteopetrosis.—Mr. A. SEYMOUR-JONES.

The meeting will be reported in the *Journal of Laryngology*.

March 1, 1957]

A DISCUSSION on **The Larynx in Rheumatoid Arthritis** was opened by **Mr. A. Young, Dr. C. S. Darke** and **Dr. L. Wolman.**

Mr. P. Scott, Mr. J. W. S. Lindahl, Mr. H. V. Forster, Mr. J. A. B. Thomas, Mr. T. Levitt and **The President** took part in the subsequent discussion.

Mr. C. P. Wilson read a paper on **Treatment of Choanal Atresia** which was discussed by **Mr. S. W. G. Hargrove, Mr. H. D. Brown Kelly** and **Mr. A. G. Gibb** (to be published in the *Journal of Laryngology*).

Section of Proctology

President—RONALD W. RAVEN, O.B.E., T.D., F.R.C.S.

DISCUSSION ON ARGENTAFFINOMA

Dr. P. S. Macfarlane (Department of Pathology, University of Glasgow, at Western Infirmary, Glasgow): *The Pathology of Argentaffinoma: The Use of 5-HIAA Estimation in Diagnosis*

Pathology.—A brief review of the pathological features of argentaffinomata or carcinoids is justified by the recent interest which has been aroused in these uncommon tumours by the discovery that they secrete 5-hydroxytryptamine (5-HT). An excess of this substance in the circulation is responsible, in some cases, for a striking clinical syndrome (Biörck *et al.*, 1952; Thorson *et al.*, 1954).

Incidence.—The tumours are most commonly encountered in the appendix but in this situation they are usually of no great importance since they are removed when too small to cause endocrine effects and to metastasize. Although these tumours have been reported throughout the alimentary tract, in the gall-bladder, biliary passages, pancreas, and in ovarian teratomata, the most common site outside the appendix is the ileum where they are often multiple.

Carcinoids occur at all ages except in the appendix where juveniles are usually affected. In my own series of non-appendicular cases the age extremes are 19 years and 83 years. It should be remembered, however, that the slow growth of these tumours probably vitiates the correct assessment of age incidence.

Ætiology.—The tumours have not been produced experimentally and there is no evidence of any external carcinogen being involved. The facts, that they occur at an early age and that they have been associated in some instances with developmental anomalies elsewhere in the body (Spain, 1955), have been used to support the view that carcinoids are developmental tumours. Many cases do, however, satisfy the usual criteria of malignant neoplasia and this interpretation seems the most reasonable at the moment.

Histogenesis.—The tumours are generally considered to arise from the argentaffin (or Kulschitsky) cells of the alimentary tract. These cells lying deep in the crypts are seen, after formalin fixation, to contain granules which characteristically give the following main histochemical reactions: (1) they spontaneously reduce silver salts; (2) they give a striking orange colour with the diazonium reaction (Pearse, 1953) this method has been found most useful in routine practice; and (3) they fluoresce brilliantly in ultraviolet light. By histochemical methods Barter and Pearse (1955) have shown that the Kulschitsky cells almost certainly contain 5-hydroxytryptamine in some form.

Appearances.—In the ileum the commonly encountered features are multiplicity, a yellow colour, a tendency to occupy the submucous layers without ulcerating into the lumen and, frequently, an association with a greater amount of hypertrophy of the bowel muscle than might be anticipated on the basis of mechanical obstruction alone. The naked-eye characters are not diagnostic and recourse must be made to microscopy in many cases. Dukes (1946) has shown that most of the carcinoids in the rectum and colon are benign and mimic in appearance the more common simple neoplasms of the region, often presenting as sessile projections into the lumen. In contrast, Gabriel and Morson (1956) have described a deeply ulcerating argentaffinoma of the rectum with lymphatic and liver metastases.

Histology.—In the majority of cases the morphological features are characteristic. The cells are in compact, rounded, aggregates often showing a tendency to peripheral palisading. Tubular and acinar formations are usually not prominent. With hæmalum and eosin staining the round uniform nuclei show a characteristic fine dusting of the chromatin while the specific granules, in highest concentration in the peripheral cells of the aggregates, are eosinophilic. Positive results are usually obtained with the histochemical reactions already mentioned. Some cases may lack these characteristics, however, and histological diagnosis, even with the special stains, may be difficult or impossible. Gabriel and Morson (1956) suggest that the large bowel carcinoids are somewhat different from those occurring at other sites in that they show poorer specific granulation and have a tendency to form tubules and acini.

Criteria of malignancy and metastases.—The smallest tumours show infiltrative features and often local lymphatic permeation but again the characteristic slowness of growth means that, in practice, the majority behave in a benign fashion despite the histological indications of malignancy. This is true particularly of the appendicular and large intestinal sites. The ileal carcinoids often have metastasized to the local lymph nodes and even to the liver, by the time laparotomy is done, but in such cases, the slow growth of the metastases is often so prominent a feature that very long survival periods are the rule.

Transcœlomic spread to the ovaries and also systemic dissemination to bones and other organs occur.

Studies on the excretion of 5-hydroxyindole acetic acid (5-HIAA) in cases of argentaffinoma.—5-HT is derived from the essential amino acid tryptophan and is broken down by the widespread enzyme amine oxidase to give 5-HIAA. The greater part of 5-HT formed in the body is excreted as 5-HIAA which can be comparatively simply estimated in the urine. The normal excretion is within the range of 3–14 mg./24 hours. Determination of urinary 5-HIAA has proved a useful method for detecting 5-HT over-production, and several cases have been studied (Macfarlane *et al.*, 1956).

Table I summarizes the findings in cases of argentaffinoma in which it was known that

TABLE I.—PROVED ARGENTAFFINOMATA

Case No.	Clinical			Site	Excretion of 5-HIAA (mg./24 hours)
	Flushing	Pulmonary stenosis	Diarrhœa		
1	−	−	±	Small bowel and liver	688 594
2	+	−	−	Ileo-cæcal and mesentery NOT liver	155
3	+	−	±	Ileum and mesentery NOT liver	65 90 84
4	++	+	+	Ileum, mesentery and liver	258 269
5	−	−	−	Ileo-cæcal and mesentery NOT liver	43

tumour tissue had not been eradicated by operation. The urinary excretion of 5-HIAA is significantly increased in them all and yet this is not associated with any constant clinical picture or with a particular distribution of tumour tissue. The findings, however, indicate that the assay of urinary 5-HIAA is useful in diagnosis.

Table II summarizes the findings in several cases in which the diagnosis of argentaffinoma seemed possible. Case 6 is particularly interesting and has been reported elsewhere (Smith *et al.*, 1957). In it the high urinary excretion of 5-HIAA confirms the tentative clinical diagnosis of argentaffinoma in spite of negative histochemical tests on tumour material from the liver and a bony metastasis. The latter tissue was, however, shown to contain a high content of 5-HT.

In the other cases in Table II the normal excretion of 5-HIAA, of course, suggests that they are not cases of argentaffinoma.

TABLE II.—THE DIAGNOSTIC USE OF 5-HIAA EXCRETION

Case No.	Clinical data	Pathology	Excretion of 5-HIAA (mg./24 hours)
6	Flushing ++ Secondary tumours in liver and bone Primary not known	Histology not clearly argentaffinoma Specific stains negative	140
7	Subacute intestinal obstruction: surgical diagnosis carcinoid	Biopsy inadequate	11·2 9·1
8	Multiple colonic tumours	3 adeno-carcinomata 1—? argentaffinoma Specific stains—negative	11·3
9 10 11	Cases of flushing and cyanosis of unknown origin	—	less than 10
12	Spasmodic flushing: Mass in right iliac fossa	—	5·2

The assay of 5-HIAA in urine is also indicated in cases of argentaffinoma after surgical treatment, but in such circumstances the sensitivity of the test, in terms of its ability to indicate early metastatic growth, has not yet been established.

Mr. Adam N. Smith (Department of Surgery, University of Glasgow, at Western Infirmary, Glasgow). (*See Scot. med. J.* (1957), **2**, 24.)

We (Smith *et al.*, 1957) have recently had the opportunity of examining the humoral effects of 5-hydroxytryptamine (5-HT) in 7 cases of metastasizing ileal argentaffinoma. The cases were showing in whole or in part the striking clinical picture of flushing with cyanosis, diarrhœa, cardiac defects and occasional asthmatic-like attacks, now well recognized since its description by the Swedish workers from Malmö. All the cases were excreting very large quantities of 5 hydroxyindole acetic acid (5-HIAA), the oxidation product of 5-HT and numerous other indole compounds (Macfarlane *et al.*, 1956; Dalgliesh, 1956).

A. Metabolism of 5-HT in relationship to tryptophan nicotinic acid and dietary protein and fat

(*i*) *Tryptophan and protein.*—Normal individuals excrete 2–10 mg./day 5-HIAA: true endogenous 5-HT production is probably higher 10–20 mg., requiring a similar amount of tryptophan as precursor. The tryptophan intake of a normal adult is usually 500–1,000 mg./day, greatly in excess of the amount required for 5-HT formation. In cases of argentaffinoma excreting up to 500 mg./day, a major part of the tryptophan metabolism may be utilized in the pathway of 5-HT formation. The metabolic aspects of one case were examined in detail by Drs. C. E. Dalgliesh and R. W. Dutton as follows:

On a protein intake of 82 grams/day the patient was in positive nitrogen balance. Nitrogen balance became negative on reducing protein intake to 31 grams/day; it was not restored by adding 500 mg. *L*-tryptophan/day to the 31 grams protein diet, but returned to its previous positive value on returning to the 82 grams protein diet. The negative nitrogen balance was therefore not due to a simple tryptophan deficiency. On the 82 grams/day protein diet, mean 5-HIAA excretion was 312 mg./day. This dropped to a mean of 224 mg./day on the 31

grams/day protein diet, rose to a mean of 301 mg./day on supplementing the diet with 500 mg. *L*-tryptophan and returned to a mean of 222 mg./day on returning to the low protein diet. The 500 mg. *L*-tryptophan/day added to the diet corresponded to the estimated tryptophan content of the 51 grams/day drop in protein content of the diet between the two stages. Of this 500 mg. tryptophan, approximately one-fifth appeared as urinary 5-HIAA. It follows that a larger amount than this was probably metabolized by the 5-HT pathway. On the low protein diet the tryptophan intake was only of the order of 300–400 mg./day and probably more than two-thirds of this was metabolized by the 5-HT pathway.

These findings are best explained by assuming that the tumour has a basic rate of production of 5-HT, and will draw on circulating plasma tryptophan till this basic production is satisfied. Increase in available tryptophan may increase the rate of production of 5-HT by the tumour slightly, but not in proportion to the increased availability. Until the basic tumour production of 5-HT is satisfied the tumour may exert priority for available circulating tryptophan over protein biosynthesis and at low levels of protein intake an argentaffinoma may seriously impair the nutritional status of a patient.

(*ii*) *Nicotinic acid deficiency.*—Tryptophan is a precursor of nicotinic acid. If excess production of 5-HT by tumour tissue were to take priority for available supplies of tryptophan over protein synthesis and nicotinic acid formation, a serious nutritional deficiency might result. In fact pellagra-like symptoms have been claimed in this syndrome (Thorson *et al.*, 1954; McNeely and Jones, 1946). One of our cases showed symptoms which could well be those of nicotinic acid deficiency. She had had diarrhœa intermittently for two to three months. Another patient complained of recurrent mouth ulcers with violet discoloration of the extremities.

The average diet in this country contains enough tryptophan to supply large demands by a tumour for 5-HT synthesis and yet still have enough for ordinary protein anabolism and nicotinic acid synthesis as well. In addition, patients with argentaffinomatosis may have diarrhœa and it seems likely that this may be important as a cause of the deficiency.

(*iii*) *Evidence for alimentary control of release of 5-HT by fat, &c.*—Bleehen (1955) claimed that a fatty meal in his patient not only caused flushing but also raised the excretion of 5-HIAA. The time relations were such that a direct effect on the tumour of the products of absorption seemed unlikely: what seemed probable was the production in the stomach or duodenum of some intermediate hormone liberating 5-HT. It seemed important to confirm Bleehen's findings since by analogy it could be postulated that the discharge of 5-HT by the normal argentaffin cell might depend on a similar stimulus.

Four patients were placed on a high fat diet for five days each. There was a substantial fall in 5-HIAA excretion and it is thus disappointing not to be able to confirm Bleehen's observation.

B. Trial of antagonists and 5-HT releasing agents

Brominated lysergic acid (B.O.L.) (Cerletti and Rothlin, 1955) antagonizes 5-HT without the disturbing effects on cerebral function of the other related drugs.

It had little effect clinically on our cases; in one case there appeared to be a definite diminution of 5-HIAA excretion. Continuous administration of reserpine provoked an overall increase in frequency and intensity of flushes and frequency of bowel movements. There was a marked rise of 5-HIAA, followed by a fall in 5-HIAA excretion indicating a period of relative depletion in the tissues. This agent may prove useful as a provocative test in the non-secreting cases.

C. Blood and urinary levels of 5-HT and related compounds

Despite rapid conversion to 5-HIAA, a high blood level of 5-HT was found in all secreting cases (1–3·2 μg./ml.: normal range 0·08–0·6 μg./ml.). Despite the large numbers of indole compounds in the urine, in the typical case, 5-HT itself is not present or detectable, nor is the precursor 5-hydroxytryptophan (5 Htp). In one exceptional case with multiple metastases 5-HT and 5 Htp were both present in considerable amount in the urine. This represents a striking confirmation for the human subject of the accepted biochemistry of the condition, precursor, active substance and breakdown product having presumably "leaked out" together into the urine from a renal metastatic site.

D. Finally a unique feature of the syndrome must surely be its protean nature; our cases presented as, or could have been confused with, subacute intestinal obstruction with diarrhœa, ulcerative colitis, Raynaud phenomenon, cardiac defects, multiple sarcomata, oliguria and menopausal flushing.

Mr. I. S. R. Sinclair (Department of Clinical Surgery, University of Edinburgh):

Some Aspects of Intestinal and Renal Function in Metastasizing Argentaffinoma

The striking humoral effects associated with argentaffinomata are found only when metastasis has occurred and are even then inconstant. At a stage when total eradication of

the tumour may be achieved by surgery we must rely for diagnosis on the local effects of the primary tumour. In the commonest site of occurrence—the appendix—these tumours are almost invariably associated with obliteration of the lumen, although the exact relationship of the tumour to the obstruction is not entirely clear. Symptoms of appendicular colic or of appendicitis are usually present and cause the patient to have appropriate treatment before metastases have occurred. In the rectum, obstructive symptoms are rare but in more than half of the reported cases without evidence of metastases there have been abdominal symptoms that have directed attention to the rectum. The commonest single complaint has been rectal bleeding, in contrast to the rarity of hæmorrhage from carcinoid tumours in

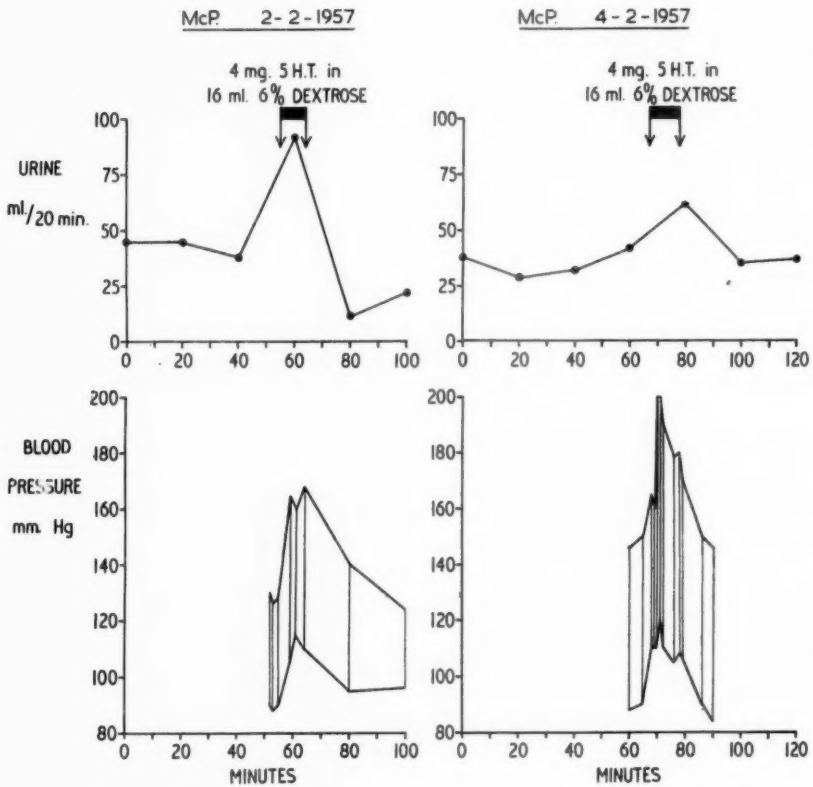

FIG. 5.—Effect of intravenous injection of 5-hydroxytryptamine on urine flow in normal subject under constant conditions.

other sites. The other principal symptoms have been rectal pain and some alteration in bowel habit.

The number of rectal carcinoids reported has more than doubled since the Section was addressed on this subject in 1950 by Mr. R. W. Raven, and the high proportion of symptomless, non-metastasizing carcinoids reported in this situation probably reflects the greater accessibility of the rectum rather than a lesser tendency towards malignancy. The most important group of tumours are those occurring in the small bowel. As with other small bowel neoplasms symptoms of disturbed intestinal function are of relatively late occurrence, and although the symptoms and signs of partial obstruction were present in almost two-thirds of 200 cases from the literature for which adequate clinical data are available,

metastases were already present in two-thirds of this obstructed group. Therefore, although argentaffinomata are particularly liable to cause intestinal obstruction, this tendency is not great enough to enhance the likelihood of early diagnosis.

Diarrhœa is less common than obstruction, being present in only one-quarter of the series of small bowel carcinoids reviewed, but is of more sinister import than obstruction in that of the 52 cases with diarrhœa all but 4 had metastases and most had hepatic as well as nodal secondaries. This suggests a predominantly humoral causation.

The characteristic feature of intestinal function in this syndrome is continuous activity of the gut. The increased motility is unrelated to the presence of obstruction and in the presence of widespread metastases continues after resection of the primary tumour. Increased

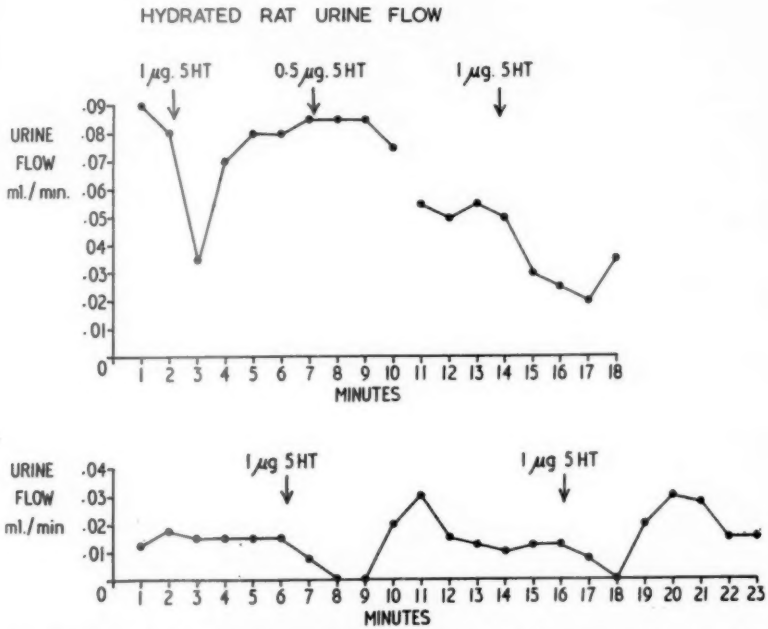

FIG. 6.—Effect of instantaneous intravenous injection of 5-hydroxytryptamine on urine flow of alcohol-anæsthetized hydrated rat. Injected dose given in 1 ml. isotonic saline.

borborygmi are present even in the absence of diarrhœa. Although typical, this excessive activity is by no means pathognomonic. A test which may ultimately prove to be more selective in patients having an unusually active gut depends on the effect on the intestine of ganglion-blocking agents such as hexamethonium bromide. From preliminary observations it seems likely that in individuals with hypermotility of the gut from various causes other than an excess of 5-hydroxytryptamine, peristalsis can be temporarily arrested by doses of these drugs that will not abolish peristalsis in patients with argentaffinomata. This is in keeping with the work of Robertson (1953) and of Rocha e Silva and Ribiero do Valle (1953) who showed that hexamethonium does not antagonize, and may even augment, the effect of 5-hydroxytryptamine on the guinea-pig ileum.

The occasional association of pellagra with the syndrome of metastasizing argentaffinoma has been noted. Of the 5 patients with this syndrome whom I have seen, none has had severe diarrhœa and none has shown any evidence of nicotinic acid deficiency. The patient with severe pellagra and metastasizing argentaffinoma recorded by McNeely and Jones (1946) was passing up to 20 stools daily. One of the cases reported by Smith *et al.* (1957) showed signs and symptoms compatible with pellagra and this patient had suffered from diarrhœa for several months. It seems likely that the diarrhœa rather than the metabolic parasitism of the tumour is the principal factor in the development of a deficiency state. It is possible,

too, that 5-hydroxytryptamine may prove to have some more direct relation to pigment metabolism than through its occasional association with pellagra.

A patient of Sir James Learmonth with an abdominal mass which proved to be a metastasis from an ileal carcinoid had a daily urine output of from 500 ml. to 700 ml. in the absence of any evidence of fluid retention. This observation, in the light of Erspamer and Ottolenghi's (1952) work in which they found 5-hydroxytryptamine to be highly antidiuretic, first led me to suggest that disturbances of renal function and, in particular, periodic oliguria, might constitute yet another facet of this syndrome. A search of the literature lent scant support to this idea. In the few cases where urinary findings have been recorded they have been unremarkable except in some rare instances of direct involvement of the urinary tract by the pathological process, as in the classical case shown by Sir Maurice Cassidy in 1930. The solitary exception to this statement is the case reported by Snow *et al.* (1955) in which attacks of flushing and weakness were associated on at least one occasion with complete anuria lasting for four hours. In April 1956 I had the opportunity of visiting Professor Waldenström's clinic in Malmö where the significance of the syndrome was first recognized (Thorson *et al.*, 1954), and found that a number of their patients had showed periods of oliguria lasting for five or six days during which the urinary output approached the "volume obligatoire". A similar observation has recently been reported by Smith *et al.* (1957). There does not seem to be any correlation between severity of symptoms and the occurrence of oliguria although in Smith's cases the oliguria was noted in the 2 patients having the most severe vasomotor manifestations. Renal function tests carried out in the 5 cases available to me have not disclosed any particular deviation from normal except in 1 patient with right ventricular failure.

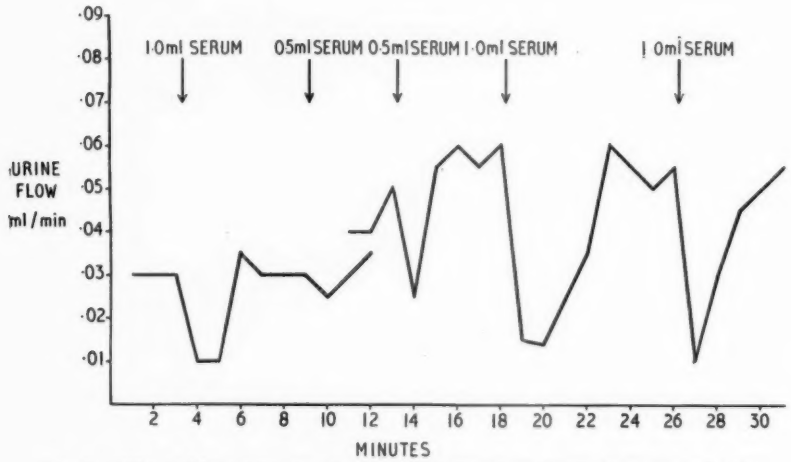

FIG. 7.—Effect of instantaneous intravenous injection of serum from patient with metastasizing argentaffinoma on urine flow of alcohol-anæsthetized hydrated rat.

To investigate further the possible antidiuretic activity of 5-hydroxytryptamine in man, I observed the effects on maximal water diuresis of reserpine, which is believed to release 5-hydroxytryptamine, and later of 5-hydroxytryptamine itself. The technique used was the rapid intravenous infusion of isotonic dextrose in a volume equal to about 2% of the total body water (in practice about 850 ml.). Urine was collected at thirty-minute intervals throughout the experiment. Whereas in normal subjects an intramuscular injection of reserpine in doses of 1 mg. to 2 mg. given one or two hours before the test did not modify the diuretic response in any way (Fig. 1), the same test in patients suffering from metastasizing argentaffinoma revealed a consistent reduction in the total response (Fig. 2). It was not possible to detect any significant change in the urinary output of 5-hydroxyindole acetic acid as a result of the injection of reserpine in this dosage.

The dose of 5-hydroxytryptamine which can be given by intravenous injection in man is limited by the unpleasant subjective sensations (tightness in the chest, flushing and tingling and increased bowel and bladder activity) and by the development of extrasystoles. When

doses up to the limit of tolerance were given by slow intravenous injection simultaneously with a water load in normal subjects no significant modification of the pattern of diuretic response was observed although the duration of diuresis tended to be shortened (Figs. 3 and 4). Because inhibition of a maximal water diuresis requires very great antidiuretic activity the effects of 5-hydroxytryptamine were tested during constant secretion at lower rates. The response was negative (Fig. 5).

In view of these equivocal results the earlier experimental work was reviewed. Most of this work was based on the subcutaneous injection of the test substance in conscious rats (Erspamer and Ottolenghi, 1952). Not only are subcutaneous injections unreliable in the assay of antidiuretic activity but 5-hydroxytryptamine tends to be extremely painful when injected, and any painful stimulus will produce powerful antidiuresis. In the only reported experiments in which intravenous injections of 5-hydroxytryptamine have been given to anæsthetized rats antidiuresis was not observed (Ames and Van Dyke, 1952). In these experiments urine collections were made at ten-minute intervals, and it appeared worth while to repeat this work using more sensitive methods. This was done in conjunction with Mr. H. A. F. Dudley, using a modification of the method described by Jeffers *et al.* (1942). The test substance is injected into the femoral vein of the alcohol-anæsthetized hydrated rat, the rate of urine flow being measured by the rate of advance of the meniscus along a micropipette attached to a cystostomy tube after ligature of the urethra. In this highly sensitive preparation the effect of 5-hydroxytryptamine was constant and reproducible (Fig. 6). Within ten seconds of injection there was a sharp drop in the rate of urine flow but this effect always passed off within three minutes. Moreover, whereas serum from a normal individual did not have any effect on this preparation, serum from a patient with metastasizing argentaffinoma had an effect comparable to that produced by 5-hydroxytryptamine (Fig. 7).

The doses of 5-hydroxytryptamine necessary to produce this transitory effect (in the order of 0·5 μg./100 grams) were comparable to those found by Erspamer and Ottolenghi (1953) to have a prolonged and profound antidiuretic effect.

Taken in conjunction with Abrahams' and Pickford's (1956) carefully controlled studies which failed to disclose in dogs any antidiuretic effect from doses of 5-hydroxytryptamine which did not also produce marked reflex disturbances of respiration and vasomotor activity, these results suggest that Erspamer's (1954, 1955) concept of 5-hydroxytryptamine as a specific renal hormone is unlikely to be correct. Whether the occasional periodic oliguria observed clinically is related to a direct effect of 5-hydroxytryptamine remains for the present uncertain.

Dr. J. **Boyland** and Dr. D. C. **Williams** (Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital, London): ***Tryptophan Metabolism in Patients with Carcinoid and Other Tumours***

The characteristic biochemical abnormality of argentaffinomas is the conversion of tryptophan to 5-hydroxytryptamine or serotonin. Many bacteria convert tryptophan into indole

which at one time was thought to play a role in intestinal cancer, but this is still uncertain. Indolylacetic acid, which is produced from tryptamine, is the plant growth hormone auxin B. In cases with a rare metabolic disease, Hartnup disease, indolylacetic acid is excreted to such an extent that a shortage of tryptophan for nicotinic acid formation occurs (Baron *et al.*, 1956). The ensuing nicotinic acid deficiency is often associated with pellagra-like symptoms. Patients with Hartnup disease resemble those with carcinoids in that they sometimes develop pellagra-like symptoms.

The major metabolic pathway of tryptophan in normal mammals leads through kynurenine, 3-hydroxykynurenine 3-hydroxyanthranilic acid to nicotinic acid. We have been particularly interested in this process because 3-hydroxyanthranilic acid is carcinogenic when implanted in the bladders of mice and it may be a cause of cancer of the bladder in man (Allen *et al.*, 1957). A subsidiary metabolic route involving 3-hydroxykynurenine leads to formation of xanthurenic acid—a substance which is said to induce hyperglycæmia and may be important in diabetes.

Our own approach to the carcinoid problem has been through interest in those tryptophan metabolites which may be of importance in cancer of the bladder. We (Boyland *et al.*, 1956) have developed a method in which some 16 tryptophan metabolites were separated on paper chromatograms and their amounts estimated by the measurement of the areas of the spots produced by the different substances.

In most of the patients twenty-four-hour specimens of urine, collected under normal conditions and following administration of 2 g *L*-tryptophan, were examined. The administration of tryptophan reduces the variation in tryptophan intake due to differences in diet and increases the amounts of the metabolites excreted, so that abnormalities in excretion patterns are more easily seen.

The method applied to 3 patients with carcinoids gave results similar to those found by other workers. The urine of these patients did not contain abnormal amounts of any of the other possible tryptophan metabolites including anthranilic acid, 3-hydroxyanthranilic acid, 5-hydroxyanthranilic acid, 3-hydroxyanthranilic acid sulphuric ester, kynurenine, 3-hydroxykynurenine, tryptamine, and indoxyl sulphate.

The same tryptophan metabolites have been determined in the urine of patients with tumours of different sites. Patients with bladder cancer excrete increased amounts of 3-hydroxyanthranilic acid and 3-hydroxykynurenine (Boyland and Williams, 1956). In investigation of these substances it was found that patients with carcinomata of the vocal cord, pyriform fossa or bronchus excreted somewhat more 5-HT or 5-HIAA than did other patients, following administration of 2 g *L*-tryptophan. The amounts excreted were small compared with those of carcinoid patients but more than excreted by patients with cancer of the bladder or cancer of the breast or by subjects free of malignant disease. Excretion of 5-HIAA by a patient with cancer of the bronchus has recently been described by Harrison *et al.* (1957). The administration of *L*-tryptophan to subjects before the collection of urine for examination undoubtedly increases the possibility of detecting metabolic abnormalities.

Professor D. F. Cappell (Department of Pathology, University of Glasgow, at Western Infirmary, Glasgow) commented on the notable hypertrophy of the smooth muscle of the ileum at the site of an argentaffin tumour and suggested that this might be attributable to a local effect of serotonin liberated by the neoplasm. Ileal carcinoids were, in his experience, usually multiple and very commonly spread to the mesenteric nodes and liver, whereas he had not seen a rectal carcinoid spread in this way. With regard to the case described by Drs. Macfarlane and Smith, he had studied the histology of the metastatic deposit in the humerus, and confirmed that in spite of its secretory activity it lacked the spceific histological characters that one associated with argentaffinoma.

DISCUSSION ON AMENORRHŒA AND HIRSUTISM

Dr. J. H. Rey:

Amenorrhœa and Psychiatric States

The problem of menstrual disorders in psychiatric illnesses is of interest from at least two aspects. Firstly, there is a higher incidence of amenorrhœa, irregular cycles, and irregular length and amount of bleeding in mental patients than in any other groups (Hanse, 1923; Ripley and Papanicolaou, 1942; Strachan and Skottowe, 1935). Also, there are certain abnormalities of behaviour and changes in mental state coinciding with certain phases of the cycle, e.g. premenstrual depression, higher incidence of suicides, delinquency, &c., in the luteal or premenstrual phase (Kroger and Freed, 1951; Mackinnon and Mackinnon, 1956; Rees, 1953). Further, certain psychiatric illnesses sometimes follow a periodic course parallel to the menstrual cycle, e.g. periodic catatonia. Secondly, little is known of the mechanisms by which the menstrual disturbances become operative. Since it is well authenticated that certain types of disorder such as amenorrhœa can follow on an emotional disturbance (Kroger and Freed, 1951), presumably some psycho-physiological mechanism possibly functioning at the hypothalamic-pituitary level is involved in the process. Such a hypothesis was put forward by Reifenstein (1946) to explain his findings in so-called cases of "psychogenic" or "hypothalamic" amenorrhœa. A number of conditions had to be fulfilled for this syndrome to be diagnosed. There should be a history of psychic trauma preceding the amenorrhœa, normal gonadotrophin excretion, defective œstrogenization of the endometrium and vaginal mucosa, failure of bleeding after progesterone administration and withdrawal bleeding following œstrogen therapy. He suggested that the defective factor was the absence of the lutein stimulating hormone which was suppressed at the hypothalamic level. However, very few endocrine studies indeed are available as to the endocrine status of psychiatric patients with functional menstrual disorders.

Objects of the Experiment

The present study was designed to investigate this problem. The investigation covered 22 patients below age 45 suffering from secondary amenorrhœa of more than two months' standing; 8 patients with irregular bleeding below age 45; 8 patients with amenorrhœa or irregular bleeding above age 45; 20 patients suffering from puerperal psychoses with amenorrhœa; and, finally, a group of 9 patients with regular periods.

Methods

Gonadal activity was assessed by daily examination of vaginal smears and cornification index counts over periods of not less than a month and up to several months in most cases. Repeated gonadotrophin estimations were done using the ultrafiltration technique; urinary 17-ketosteroids excretion was also assessed as well as the measurement of thyroid activity using the I^{131} urinary excretion method.

Findings

A. *Vaginal Smears*

(1) *Secondary amenorrhœas.*—The smears showed: (*a*) protracted phases of low and defective œstrogenization as indicated by a low cornification index, the "dirty" type of smears with small cells, debris, leucocytes and sometimes basal cells; (*b*) absence of clearly-defined progesterone effect; (*c*) absence of ovulatory smears; (*d*) presence of fluctuations in the cornification index but no regular cyclical activity; (*e*) sharp contrast with the picture found in normal cycles.

(2) *Irregular menstruation.*—Tendency to show a protracted and defective follicular phase, delayed or absent ovulation, absence of well-established progesterone effect.

(3) *Puerperal amenorrhœas.*—The smears resembled those of the secondary amenorrhœas but basal cells were more often present and in higher percentages.

(4) *Amenorrhœa and irregular bleeding above age* 45.—Two types of cases were observed: (*a*) those with a high and well-sustained cornification index but no signs of progesterone activity; (*b*) those resembling cases below age 45.

B. *Gonadotrophins*

Urinary gonadotrophin estimations showed fluctuations in the same patients from low to normal levels. Normal values were obtained for a control group of 16 psychiatric patients with regular menstrual cycles. A comparison was made between the first values obtained in the cases of amenorrhœa and irregular menstruation below age 45 and values for the psychiatric control group. The tendency to lower activity in the abnormal group was significant at the 1% level, with a mean of 6·2 m.u. for the abnormal group and 16·3 m.u. for the control group. The group of patients above age 45 showed an increased gonadotrophin activity.

C. 17-*Ketosteroids*

Repeated estimations showed fluctuating levels of excretions. A comparison of first estimations made between abnormal groups and psychiatric controls showed that for both the amenorrhœas and cases of irregular bleeding below age 45, but not the puerperal patients, there was a tendency to lower levels of excretion significant at the 1% level. The mean for the amenorrhœas and cases with irregular menstruation was 6·3 mg./twenty-four hours and that for the psychiatric control group was 9·4 mg./twenty-four hours.

D. *Thyroid Activity*

30 patients with abnormal periods or amenorrhœa were compared with a group of 24 patients with normal menstruation by the I^{131} urinary excretion test. There was no significant difference between the groups though the scatter was significantly greater in the case of the abnormal group. The distribution curve for "T" showed a slight shift to the region of low uptake for the abnormal group when compared with the psychiatric controls.

Discussion

These results can be compared with previous endocrine findings in non-psychiatric cases of functional amenorrhœa and oligomenorrhœa and with studies on psychiatric patients with similar disturbances.

With regard to the first group, the commonest abnormal finding is that of a low level of œstrogen excretion, though normal levels can be found and high levels seldom (Pedersen-Bjergaard and Tonnersen, 1951; Ripley and Papanicolaou, 1942). Gonadotrophin estimations are more often reported as being normal or low, or occasionally high (Albert, 1957; Pedersen-Bjergaard and Tonnersen, 1951). Few studies have been made of the full endocrine picture of these patients. Similarly, reports about œstrogen and gonadotrophin excretion often refer to single estimations. With regard to the gonadotrophins, this is looked upon as a serious drawback by Albert (1957) in his thorough review of the subject as daily fluctuations and rhythmical variations may exist even in amenorrhœa. As to vaginal smear findings, Allende and Orias (1950) report similar findings to those of the present study.

With regard to psychiatric studies, Reifenstein's hypothesis has been referred to. Ripley and Papanicolaou (1942) studied the menstrual cycles in mental patients suffering from psychoses. They did serial vaginal smear examinations and found the commonest abnormality was an atypical follicular reaction and a delayed follicular phase indicating subnormal œstrogen activity. They concluded that there was a delay in development and maturation of the follicle resulting in delayed ovulation, prolonged cycle or amenorrhœa. There was a positive relationship between severity of illness and degree of ovarian function. They declined to offer a suggestion as to the missing factor. Undernutrition was not a factor. This can also be eliminated in the present study, except in the cases of anorexia nervosa, though the menstrual disturbance is known often to precede the loss in weight in these patients.

Summary and Conclusion

In this study patients suffering from secondary amenorrhœa and irregular menstruation showed absence of ovulation, absence of progesterone activity, and defective follicular activity in the smears. There was some indication that gonadotrophic activity, 17-ketosteroids excretion and perhaps thyroid activity tended to be on the low side of normal

and differed significantly from comparative measurements in a control group. It was not possible to demonstrate whether defective gonadal activity was due to the absence of a lutein stimulating hormone, as this could not be measured. However, the above findings are in favour of a hypothesis that there is a hypothalamic-pituitary participation. The fluctuations observed over extended periods of time, and often in connexion with changes in the mental state, explain the various findings reported by different workers. It also shows that the intensity of the degree of dysfunction may vary, the gonadotrophins being the most sensitive to the disturbing process (Hubble, 1955).

This work was made possible through a grant from the Research Fund of the Bethlem Royal and Maudsley Hospitals.

Dr. B. T. Donovan:

The Hypothalamus and Gonadotrophin Secretion

Although many cases of psychogenic amenorrhœa have been described, knowledge of the mechanisms underlying this condition would seem to have advanced little beyond the suggestion of Klinefelter *et al.* (1943) that there is a disturbance of the release of luteinizing hormone (LH). This view was derived, in part, from the information then available concerning the hypothalamic control of gonadotrophin secretion in laboratory animals, and since considerable advances have been made in this field in recent years it may be useful to sketch very briefly some of the more recent findings.

It is now clear that LH may be released from the pituitary gland by electrical stimulation of the hypothalamus. This response is particularly well shown in the œstrous rabbit by the occurrence of ovulation some ten hours after the stimulus and has been described by Harris (1937, 1948), Haterius and Derbyshire (1937), Markee *et al.* (1946), and Kurotsu *et al.* (1950). Collateral evidence for the participation of neural factors in the release of LH in other species has also been produced. The blockade of ovulation in the rat (Everett, 1952), the advancement of ovulation by coitus in the cow (Marion *et al.*, 1950), the modification of œstrous cycle length by uterine distension in the ewe (Nalbandov *et al.*, 1955), and the blockade of ovulation in the hen (van Tienhoven *et al.*, 1954) may all be cited as examples of the investigations which have been made.

Certain consequences of the destruction of localized areas of the hypothalamus may be interpreted in terms of an interference with the release of LH. Dey *et al.* (1940) and Dey (1943) found that destruction of a large area of the hypothalamus immediately posterior to the optic chiasma sometimes produced a state of constant œstrus in guinea-pigs. Ovulation did not occur and the ovaries contained only large follicles. This result was subsequently confirmed in the rat by Hillarp (1949) and Greer (1953) who used rather smaller lesions in the neighbourhood of the paraventricular nuclei. It appears from these experiments that although ovulation was suspended some LH was being released from the pituitary glands of the constantly œstrous rats because the interstitial cells of the ovaries did not show the changes indicative of lack of LH. Greer (1953) also made the observation that progesterone given daily was able to produce ovulation in rats displaying constant œstrus and permit the resumption of œstrous cycles. The finding that smaller doses of progesterone, below those producing ovulation, still were able to interrupt the persistent œstrus of rats with hypothalamic lesions led Alloiteau (1954) to postulate that the steroid inhibited the release of follicle stimulating hormone (FSH). This worker believed that the œstrogen level in the rat made constantly œstrous was insufficient to block the secretion of FSH. Flerkó (1954) has shown that hypothalamic lesions which produce constant œstrus in rats interfere with a feed-back action of œstrogen, so that the condition would seem to result from an excessive release of FSH.

The suggestion that electrolytic lesions in the anterior hypothalamus interfere with the regulation of FSH discharge receives support from recent work on the ferret. Donovan and van der Werff ten Bosch (1956*a*) have demonstrated that lesions placed just behind the optic chiasma in sexually quiescent animals in winter resulted in the onset of œstrus in about four weeks, long before blank operated control animals came into heat and at an abnormal time of the year. In these experiments it is clear that FSH is being released from the hypophysis in increased amount and it has been suggested that the lesion interferes with a mechanism inhibiting the secretion of FSH. Since the lesions were anterior to the median eminence the result cannot be attributed to the release of stored hormone following interference with the blood supply of the pars distalis, and an irritative effect of the lesion can perhaps be discounted because electrical stimulation of the anterior hypothalamus has so far failed to advance the onset of œstrus.

The existence of a mechanism inhibiting the release of gonadotrophic hormone has previously been postulated in explanation of the condition of pubertas præcox in children (Weinberger and Grant, 1941). However, few attempts have been made to test this concept experimentally. Clinically, the majority of tumours advancing puberty are located in the posterior hypothalamus and hence the action of lesions placed in this region has been studied, so far without any positive result (Bustamante, 1943; Gaupp, 1950). In view of the findings in the ferret the effect of lesions placed in the anterior hypothalamus of infantile rats was also investigated by Donovan and van der Werff ten Bosch (1956*b*). Small mid-line lesions were placed in the anterior hypothalamus of nine 14- or 15-day females and the animals examined regularly for vaginal opening. Two lesioned rats reached puberty at 30 days of age and four at 33 days. In one of eight sham-operated animals vaginal opening was noted on the 33rd day, but as all the rats were killed on the 20th day after operation observations on the other control animals could not be made. Study of a series of twenty-six normal rats revealed that only one animal reached puberty at 33 days, whilst the average age for puberty was approximately 41 days. Since this initial experiment lesions have been placed in a further series of rats and the findings in the first experiment have been confirmed. The vaginal smear has been followed in the second series and it is of interest that persistent œstrus has been found in some, but not all, of the lesioned rats in which puberty was advanced.

In considering the above experiments it seems possible that the hypothalamus is able to exert a restraining influence on the secretion of gonadotrophic hormones with perhaps a feed-back action of the gonadal hormones playing an important part in this mechanism. However, it would be unwise to suggest that the hypothalamic lesions producing constant œstrus in the rat, advancing the onset of œstrus in the ferret and causing precocious puberty in the rat, all interfere with a common mechanism. The fact that normal reproductive function and persistent œstrus can both be seen in rats in which puberty was hastened by hypothalamic damage points to caution in this respect.

Dr. P. Kynaston Thomas and **Dr. David Ferriman:**

Constitutional Virilism

The investigations summarized in this paper began as an enquiry into the relationship between hirsuties and infertility in women. For a variety of reasons the assessment of infertility proved a matter of considerable difficulty and no definite conclusions could be reached. During the course of the investigation, however, a number of points emerged which were considered to be of interest.

At the outset of the investigation it was realized that there was no clear demarcation between hirsute and non-hirsute subjects. Growth of body hair varies widely both in men and women, and in fact appears to be a graded characteristic. It therefore became necessary to devise a system for grading the degree of hair growth. Of the various possible sites three were selected for study: the upper lip, the chin and lower abdomen. Five grades of growth were recognized at each site. Grade 0 represented the absence of hair. Minor degrees of hirsuties were common and were classified as Grades 1 and 2. More severe degrees, approximating to the popular conception of hirsuties, were less common, and were categorized as Grades 3 and 4.

An investigation into the variation in the incidence of hirsuties at these three sites and its variations with age was made on a series of approximately 600 female hospital patients between the ages of 15 and 84 seen in the general medical, general surgical and tuberculosis wards, one geriatric ward and one medical out-patient clinic at the North Middlesex Hospital. The series was unselected except in so far as diseases known to have effects on hair growth, such as myxœdema, were excluded. The results of this investigation are to be reported in full elsewhere (Thomas and Ferriman, 1957). Some features are of interest in the present connexion. A grading of 0 is clearly the most frequent finding in the pre-menopausal age groups, being found on three out of four occasions at any one site. Minor degrees of hirsuties are quite common. Major grades occur less frequently but still in significant numbers, being found at one or more sites in approximately 10–15% of individuals. The enquiry further revealed that these major forms of hirsuties first became apparent in the great majority of instances during adolescence. Striking changes take place in hair growth in the post-menopausal period of life. A marked increase occurs in the incidence of facial hirsuties, while hair virtually disappears from the lower abdomen.

The relationship between hirsuties and hair colour was also examined. Although the incidence of dark hair was slightly greater in hirsute than in non-hirsute subjects, the difference did not reach the level of statistical probability. The finding is in accordance with the results of previous workers.

Investigations were then carried out into the relationship between hirsuties and other masculine characteristics, and between hirsuties and oligomenorrhœa, and into the familial incidence of the condition. These investigations are being reported in full elsewhere (Ferriman *et al.*, 1957).

In order to assess whether hirsuties is accompanied by any other evidence of masculinization, measurements of shoulder and hip width and of urinary 17-ketosteroids excretion were obtained.

One of the most obvious skeletal differences between males and females is that shoulder width when expressed in terms of hip width is greater in the males. Measurements on approximately 40 subjects with a major degree of hirsuties at one or more sites demonstrated that the average bi-acromial width for these individuals was significantly greater than for a group of subjects with a zero or low hirsuties grading. Bi-iliac width did not differ between the two groups, and it is clear therefore that the observed difference in shoulder width did not depend upon differences in general body size or upon greater breadth of the trunk as a whole.

A similar comparison was made between the twenty-four-hour urinary 17-ketosteroid excretion in a group of approximately 60 patients with major grades of hirsuties and a group of subjects with zero or low hirsuties grading. The 17-ketosteroid excretion in the former group was found to be significantly greater.

The association generally believed to exist between hirsuties and oligomenorrhœa was explored during the course of the survey on the incidence of hirsuties, to which reference has already been made. Menstrual histories were taken from those patients between the ages of 15 and 44, together about 350 in number. The changes in hair distribution that are observed in later life precluded consideration of later decades. Employing strict criteria for the existence of oligomenorrhœa, a highly significant correlation between this type of menstrual disturbance and hirsuties was confirmed.

A somewhat limited enquiry was made into the incidence of hirsuties and oligomenorrhœa in the female relatives of hirsute individuals. As many mothers and sisters as possible of some 30 patients showing major grades of hirsuties were examined. Approximately 50% of both the mothers and sisters were found to have a major grade of hirsuties; this incidence,

considerably greater than that obtained in a control series, was statistically significant. Similarly there was an increased incidence of oligomenorrhœa in the relatives. These results thus confirmed the generally held belief that the condition is genetically determined.

It was concluded therefore that hirsute subjects show a distinct masculine tendency in two other directions, namely in having an increased shoulder width, and a raised urinary excretion of 17-ketosteroids. A high proportion have menstrual disturbances in the form of oligomenorrhœa. In view of the genetic background and the association of other masculine features with the hirsuties, the term constitutional virilism is suggested as an appropriate title for the syndrome.

Dr. P. M. F. Bishop and **Mr. R. D. de Vere:**

The Stein-Leventhal Syndrome

In 1929 Stein performed his first wedge-resection for polycystic ovaries. In 1935 Stein and Leventhal described the classical features of the syndrome which consists of bilateral ovarian enlargement, amenorrhœa, hirsutism, obesity and vague and intermittent lower abdominal pain. In 1949, Stein *et al.* recorded 75 cases collected over a period of twenty years, since Stein performed his first operation. In only half this number of cases were there palpably enlarged ovaries. Klinefelter and Jones (1954) point out that this is largely due to the obesity and advocate gynæcography (induction of a pneumo-peritoneum followed by an X-ray examination), culdoscopy or even laparotomy.

Secondary amenorrhœa is the characteristic menstrual disorder; the condition does not develop before the menarche. Metropathia has occurred in some cases, as a manifestation of failure to ovulate. One case has been reported by Holmer (1950) in which regular, but non-ovulatory, menstrual cycles were present. Stokhuyzen (1950) recorded a case with regular, ovulatory cycles.

Hirsutism is found in only about 50% of the cases. It is occasionally associated with virilism.

In the majority of cases there is some degree of obesity and it is marked in about half the total number of cases.

Lower abdominal pain may be the presenting symptom in some cases.

On macroscopical examination the ovaries are obviously enlarged, firm, smooth, flattened, sclerotic and bluish-white—"oyster-ovaries".

On microscopical examination there are numerous microcystic follicles; the cortex is thickened and fibrotic and there are luteinized hyperplastic theca interna cells spreading into the theca externa and even appearing as isolated islands in the dense ovarian stroma.

The 17-ketosteroids were raised in only 5 out of 29 cases collected by Dorfman and Shipley (1956) and in 3 out of 5 cases studied by Bergman (1954).

Urinary gonadotrophins and œstrogens show normal values.

Fischer and Riley (1952) found a persistently raised urinary pregnanediol level in one case (though doubt has been cast on their method of estimation) and they postulate an excessive production of progesterone by the thecal cells leading to a suppression of production and release of luteinizing hormone which would hinder ovulation, though there might be a continuous production of follicle stimulating hormone, which might account for the microcystic follicles.

It may, however, be significant that the ovarian lesion is bilateral and Culiner and Shipel (1949) postulate that there is excessive production of luteinizing hormone to account for the ovarian hyperthecosis. In one of their cases ovarian enlargement developed only after administration of chorionic gonadotrophin for some menstrual irregularity.

Ingersoll and McDermott (1950) emphasize the "collagenous infiltration of the ovarian capsule" and regard this as a mechanical barrier to ovulation. This might explain the beneficial effects of wedge resection. It has even been found that bisecting the ovaries and sewing the two portions back to back gives equally satisfactory results.

Whatever the pathogenesis of the syndrome may be the results of wedge resection are most dramatic. Stein *et al.* re-established normal, ovulatory menstrual cycles in 67 of their 75 cases and conception followed within a few months in 26 of their 40 patients complaining of infertility.

There is, however, unfortunately, seldom any regression of hirsutism.

The object in presenting the following two cases of the Stein-Leventhal syndrome is to show that this syndrome may exist in the absence of many of the signs and symptoms originally described, and in the presence of other features, which by the same token would seem

to exclude it. The already well-recognized success of wedge resection of the ovaries in these cases is also clearly demonstrated.

Case I.—Mrs. W., aged 21. Married. Nulliparous.

This patient was referred to the Endocrine Clinic at Chelsea Hospital for Women from a Maternity Hospital which she had attended under the impression that she was pregnant. Her complaints were: (1) Amenorrhœa for one year, her menstrual periods having been regular and normal before this. (2) Increasing hirsuties for the past four months. (3) Rapid increase in weight over the past seven months. (4) Inability to become pregnant during the two years of her marriage.

Examination showed that she was a markedly obese young woman of normal stature with dark hair. She had pronounced "side-whiskers" extending to the angles of the jaw, and an obvious moustache which she made no attempt to disguise. She had marked hirsuties of the breasts, abdomen and thighs and the pubic hair was of the so-called "male" type. There were no other masculinizing signs. Owing to her obesity, pelvic examination was difficult, but the uterus appeared to be normal in size. What was assumed to be the enlarged left ovary could be felt but the right ovary was not palpable.

B.P.: 120/80. *Urine:* No sugar. 17-*ketosteroids:* 12·6 mg./twenty-four hours.

Examination under anæsthesia showed both ovaries to be symmetrically enlarged and this was confirmed at *laparotomy* when the typical sclerocystic ovaries were found. They measured approximately 5 × 3 × 2 cm. each. Five-eighths of each ovary was removed by wedge resection and the ovaries were reconstituted with an atraumatic suture.

Section of the ovarian tissue showed all the characteristics of the Stein-Leventhal ovary.

Regular ovulatory menstrual cycles were resumed two months after the operation, and the patient has since delivered a normal child at term. Her weight and the extent of the hirsuties are unchanged.

Case II.—Miss E., aged 33. Unmarried. Nulliparous. Her complaints were: (1) Hirsuties for fifteen years becoming progressively worse. (2) Baldness for the same time, also getting worse, and for which she wore a wig. (3) Irregular, infrequent and prolonged menstrual periods for five years, these having been normal and regular before this.

Examination showed that she was a young woman of normal stature and contour. She was not obese. There was generalized facial hirsuties effectively disguised by electrolysis, plucking and liquid make-up. She wore a wig to conceal marked baldness of the tonsure type and some recession at the temples. There was moderate hirsuties of the breasts, abdomen ("male type" pubic hair) and legs.

Both ovaries were palpably enlarged on pelvic examination.

B.P.: 130/75. *Urine:* No sugar. 17-*ketosteroids:* 9·2 mg./twenty-four hours.

On examination under anæsthesia both ovaries were found to be symmetrically enlarged. *Curettage* produced abundant endometrium which on section showed cystic glandular hyperplasia.

At laparotomy typical Stein-Leventhal ovaries were found, each measuring approximately 6 × 4 × 2 cm. Wedge resection was performed as in Case I.

Since operation (twenty months) she has had normal, regular menstrual periods. The extent of her hirsuties has not progressed, neither has it regressed. Her baldness has improved markedly, and she has been able to discard her wig, but this may be due to the application of hydrocortisone ointment during the past year. As the result her morale has improved dramatically, and from being decidedly aggressive she is now co-operative.

The atypical features in this case (Case II) are the presence of a metropathic type of menstrual history as opposed to amenorrhœa, the absence of obesity, and the presence of baldness. As these cases are not invariably accompanied by hirsuties it may be justifiable to assume that some cases of metropathia (cystic glandular hyperplasia of the endometrium) have sclerocystic ovaries and would perhaps benefit by wedge resection of the ovaries provided the typical appearance of the ovaries was found on laparotomy.

As has been said, cases of the Stein-Leventhal syndrome vary widely in their symptomatology. There may or may not be hirsuties; obesity is not invariably present and as in Case II there may not even be amenorrhœa (Greenblatt, Holmer, Stokhuysen, Menher *et al.*). The diagnosis finally rests, therefore, on the demonstration of the characteristic condition of the ovaries.

Ovarian enlargement frequently escapes the most careful clinical examination particularly in the virgin and in the presence of obesity. In the United States culdoscopy is widely practised and would seem to be the ideal method of demonstrating minor degrees of ovarian enlargement. It is not without its difficulties, even in the hands of the expert, and the authors, in common with most gynæcologists in this country, have little experience in its use. It would be extremely valuable in a doubtful case where examination under anæsthesia had failed to demonstrate enlarged ovaries.

Similarly objections apply to the use of X-rays following the induction of a pneumoperitoneum ("pneumo-Roentgenology"), and although some very impressive X-ray photographs have been reproduced in the American literature, we have had no success with this method. Further objections are that it demonstrates only the size of the ovaries, not their consistency, and then only in relation to the size of the uterus. Also, the wisdom of irradiating the ovaries of young women of reproductive age has recently been questioned.

In the authors' view examination under anæsthesia is the most satisfactory method and we have found that with the use of relaxant drugs we have been able to feel the ovaries, enlarged or not, in all cases in question. A more difficult question to decide is whether or not the ovaries are enlarged, and in our experience laparotomy has shown them to be larger than was anticipated. We have yet to meet the case where both ovaries were impalpable under anæsthesia.

Dr. Raymond Greene protested against too wide an application of the term Stein-Leventhal syndrome and feared that we were in danger of considering that all women who were fat or hairy or suffered from any kind of menstrual disturbance were suffering from incomplete forms of the syndrome. He drew attention to the fact that although wedge resection of the ovaries corrects the menstrual abnormality and may even make pregnancy possible, it rarely, and in his experience never, helps the obesity or hypertrichosis. He quoted the case of a previously pretty Hungarian girl with the complete syndrome who came under his care after an attempt at suicide. Wedge resection had the usual result and her depression deepened. Strict dieting produced only a very slow reduction of her weight, originally 13 st. 4 lb. The output of 17-ketosteroids was normal (7·85 mg. in twenty-four hours) and was not raised by treatment with chorionic gonadotrophin. It was decided that her depression warranted extreme measures and a subtotal adrenalectomy was performed. The adrenals were histologically normal, though one was slightly enlarged (weights of excised portions 8·5 and 13·6 grams (total)). No dramatic effect followed, but a steady improvement has occurred during the two years which have elapsed. She has shaved at gradually increasing intervals, her weight without dieting has dropped to 10 st. 12 lb., and her menstruation has remained normal.

[*February* 27, 1957]

THIS Meeting of the Section was devoted to discussion of the subject matter of the recent Conference of the Ciba Foundation on **Hormones in Blood.** The speakers were Dr. M. SONNENBERG, Dr. E. B. ASTWOOD, Dr. L. T. SAMUELS and Professor C. J. O. R. MORRIS.

[*March* 20, 1957]

A JOINT MEETING was held between the Section of Endocrinology and the Society for Endocrinology. The meeting took the form of a Symposium on "Investigations on Subjects Relating to Obesity and Diabetes". An Introduction was given by Sir Charles Dodds. The titles of the papers presented were as follows:

The Effect of Age on the Somatic and Visceral Response to Over-nutrition in the Rat.—Dr. G. C. KENNEDY.

Metabolic Changes on Reducing Diets.—Dr. J. A. STRONG and Dr. R. PASSMORE.

Obesity, Parity and Diabetes.—Dr. D. PYKE.

Observations on Human Reproduction and Body Weight.—Dr. T. MCKEOWN and Dr. R. G. RECORD.

The Hypothalamus and Carbohydrate Regulation.—Dr. A. PATON.

Pituitary Growth Hormone and Blood Insulin.—Dr. P. J. RANDLE.

Insulin Activity and Antagonism in the Plasma of Diabetic Patients and Animals.—Dr. J. VALLANCE-OWEN.

The Antidiabetic Sulphonamides.—Dr. D. M. DUNLOP and Dr. L. J. P. DUNCAN.

Summing up by Dr. T. RUSSELL FRASER.

The meeting will be fully reported in the *Journal of Endocrinology*.

JOINT MEETING No. 3

Section of Pathology with Section of Physical Medicine

Chairman—Professor JOHN W. S. BLACKLOCK, M.D.
(President of the Section of Pathology.)

[*February* 19, 1957]

DISCUSSION ON RHEUMATOID DISEASE

Dr. W. S. Tegner (The London Hospital): *The Clinical Aspect*

The clinician who is interested in rheumatoid arthritis is more likely to see and discuss his patients with the clinical pathologist than with the morbid anatomist. This is due to more than one factor: the pathology of rheumatoid arthritis is not established and exact; it is also true that our patients are not suffering from a killing disease and do not come to the post-mortem table because of rheumatoid arthritis. For in this antibiotic age it is no longer possible for us to say quite so readily that our patients die of intercurrent infection. I find that my poor old cripples now get over their bronchopneumonia and continue to exist for longer periods. If we prolong the lives of our rheumatoid arthritics we must not at the same time prolong their sufferings, otherwise we increase the burden on all those who care for the crippled and incurable.

The rheumatoid arthritic who reaches the post-mortem table usually comes from a hospital bed to which she has been admitted for some other condition. Usually the rheumatoid arthritic dies at home. But if she is afflicted at the same time with some other interesting condition, the hospital will take her in when she is seriously ill. This has caused a difference in the opinion on the incidence of such a condition as amyloidosis in rheumatoid arthritis. I have looked for amyloidosis among my rheumatoid arthritics—and I have more than a thousand on my books—but I have found only one. On the other hand, the morbid anatomists at The London Hospital find an incidence as high as 25% among the rheumatoid arthritics who come into their hands. When the clinician finds he has a rheumatoid arthritic displaying some particularly interesting feature such as amyloid disease he makes sure that that patient dies in hospital. In this way the rarer and more interesting conditions associated with rheumatoid arthritis get into the hands of the morbid anatomists in far higher proportion than they are found in a living series.

Biopsy in rheumatoid arthritis.—I want to take only a few rather isolated instances, which I have met more than once. Epitrochlear adenitis is commonly seen when the arthritis involves the wrists and fingers. There is nothing unusual in such adenitis, yet the Wassermann reaction is inevitably done and has proved negative, and so a biopsy is ordered.

Another unusual point of contact between the morbid anatomist and the clinician dealing with arthritis has been in Hodgkin's disease. One patient was found to have a diffuse enlargement of the lymph glands and some other curious lumps. He was also febrile, and had a palpable liver and spleen. A diagnosis of Hodgkin's disease was made, and radiotherapy was started before a lump from the occipital region was sent for examination. The pathologist reported this to be a typical rheumatoid nodule, and naïvely enquired " did the patient exhibit any arthritis?" In this case the pathologist made the diagnosis, and it was not until he had done so that I was called in to confirm it. Last month I had a patient referred to me with the story that a mass of glands, thought to be enlarged through Hodgkin's disease, had been removed five years ago from his groin, after which he was treated by radiotherapy and got well. After three years he was not so well, and complained of general aches and pains. Finally it was decided he was suffering from rheumatoid arthritis, and he was put on cortisone, which did him neither harm nor good. He was referred to me on cortisone as suffering from rheumatoid arthritis. I could find no evidence of arthropathy and on looking at the original slide, the patient proved to be suffering from Hodgkin's disease. Though such instances of rheumatoid arthritis presenting as a differential diagnosis of Hodgkin's disease must be exceedingly rare, yet I have met such a situation twice in the last ten years.

The joints in rheumatoid arthritis.—Clinicians sometimes overstress the joint pathology and forget that rheumatoid arthritis is a general systemic disease with many extra-articular manifestations. The deformity pattern adopted by a joint depends not on the disease but on the anatomy of the affected joint; thus, I have seen extreme ulnar deviation of the fingers in classical gouty arthritis. Even in rheumatoid arthritis of the fingers ulnar deviation only occurs in about 25% of patients.

Rheumatoid arthritis presenting as a mono-articular arthropathy.—I see such patients at regular intervals in consultation with orthopædic surgeons. Usually they have been diagnosed on clinical and radiological grounds as suffering from tuberculous arthritis and surgical debridement has been advised. At operation the surgeon finds that the appearances are not those of tuberculous arthritis and sends synovial membrane for biopsy, after which his opinion that the joint is not after all tuberculous is confirmed. The patient usually develops further rheumatoid joints after this. I would have thought that a simple aspiration of joint fluid before operation would be advisable, but I suppose the vast majority of tuberculous joints are correctly diagnosed and such a pre-operative diagnostic procedure is regarded as unnecessary. It is of interest that in these days, when joint tuberculosis can be treated so admirably by a combination of surgery, chemotherapy and antibiotics, it is of much better prognosis to have tuberculous rather than rheumatoid arthritis.

Dr. Bruce Cruickshank (Pathology Department, Glasgow Royal Infirmary): *Rheumatoid Arthritis and Rheumatoid Disease*

The term "rheumatoid arthritis" implies a disease entity involving the joints, in which the changes are rheumatic-like. The clinical features in patients with "rheumatoid arthritis" are similar to those of other rheumatic diseases. Indeed, the condition is one of the most important within that group. Are these clinical features associated with specific pathological changes? The term "rheumatoid disease" is being used with increasing frequency: implying a condition not confined to the joints. Is this a clinical syndrome or a pathological entity?

Synovial Lesions

Some authors have stated that the lesions in the synovial tissue in "rheumatoid arthritis" are specific. Allison and Ghormley (1931) laid great stress on the presence of lymphocytic foci and regarded them as specific to the disease. Key (1934) described lesions in traumatic synovitis which were basically the same as those in "rheumatoid arthritis" and most other writers during that decade regarded the lymphocytic foci as non-specific. The two most recent studies of large collections of material have led their authors to opposing conclusions. Bennett (1941) found lymphocytic foci in conditions other than "rheumatoid arthritis" and concluded that the lesions of "rheumatoid arthritis" were not specific. On the contrary, Collins (1949) regarded certain changes as diagnostic of "rheumatoid arthritis", provided that the specific features of other diseases, such as tuberculosis, were absent.

The data presented here are condensed from a study of all specimens of synovial tissue from joints, bursæ and tendon sheaths received in the Departments of Pathology, University and Royal Infirmary, Edinburgh, during the period 1935–1951 and of additional material from examples of rheumatic diseases collected by the author during the period 1948–1951 (Cruickshank, 1952*a*). Table I shows the incidence, in the various diseases studied, of the complete combination of changes described by Collins, and of necrosis, which is another common feature of synovial tissue in "rheumatoid arthritis." Those examples of "rheumatoid arthritis" and ankylosing spondylitis in which old-standing fibrosis was the predominant feature (30 and 7 joints respectively) are excluded from Table I. The complete combination of changes occurs in several conditions other than "rheumatoid arthritis", some of which, such as tears of menisci, are unlikely to be confused with "rheumatoid arthritis", whereas others, such as non-specific monarticular arthritis or tenosynovitis, may be the presenting clinical feature of "rheumatoid arthritis". Indeed, a few of the examples of non-specific arthritis and tenosynovitis may have been atypical or early cases of "rheumatoid arthritis", for an adequate follow-up was not always possible; but "rheumatoid arthritis" could be excluded in most of them. In such cases histological examination cannot clinch the diagnosis. A diagnostic appearance was seen only in the occasional instance where necrosis constituted part of granulomatous foci such as occur in the subcutaneous nodule in "rheumatoid arthritis". A closer resemblance to this type of reaction ("the rheumatoid granuloma") has been reported in early synovial lesions (Kulka *et al.*, 1955) than in most of the established lesions studied here. In the absence of such foci the pathologist cannot say more than that the appearances are compatible with the diagnosis of arthritis of the rheumatoid type; final assessment of the patient must be made by the clinician.

TABLE I.—INCIDENCE IN SYNOVIAL TISSUE OF LESIONS "CHARACTERISTIC" OF "RHEUMATOID ARTHRITIS" IN VARIOUS DISEASES

Diagnosis	Number of specimens examined	Lesions of "rheumatoid arthritis" present	Necrosis present

* Tubercle follicles also present.
† Necrosis of caseous type.

VISCERAL LESIONS

The involvement of tissues other than the joints and subcutaneous tissue in patients with "rheumatoid arthritis" has been known for many years though most papers have appeared in the last fifteen years. Almost any organ or tissue may be involved by non-specific lesions, by "rheumatoid granulomata" or both. Such lesions have been encountered in hospitalized patients, who represent a selected group of sufferers from the disease. Indeed, many reports have been limited to the description of lesions found in one or two such patients. These studies give no indication of the incidence of visceral lesions in the disease as a whole, as distinct from particular groups of patients, selected for a variety of reasons. Some of the systemic lesions are associated with clinical features, such as splenomegaly, episcleritis, &c., but others are detected only at autopsy, so that the true incidence of such changes can be obtained only from clinical and pathological studies of large numbers of patients. Full details of the whole of the clinical course of the disease are not always available, which makes it difficult to assess the significance of all lesions found at autopsy.

A series of 100 autopsies on patients who had suffered from the disease provides the material for the present review of visceral lesions. 49 of these patients were admitted to hospital for treatment of "rheumatoid arthritis" or its complications, 51 for the treatment of intercurrent disease. Table II shows the incidence in various tissues and organs of lesions

TABLE II.—INCIDENCE OF SYSTEMIC LESIONS IN 100 EXAMPLES OF "RHEUMATOID ARTHRITIS"

Heart:			
endocarditis alone	4		
myocarditis alone	3		
pericarditis alone	3	18	
arteritis alone	8		
endocarditis and amyloidosis ...	1		
myocarditis and arteritis... ...	1	2	30
pericarditis and arteritis	1		
endo-, myo- and pericarditis ...	3		
endo- and pericarditis and arteritis	4	9	
myo- and pericarditis and arteritis	2		
Arteritis (in organs other than the heart)		13	
Pleuræ			42
Spleen			12
Lymph nodes			11
Muscle (in biopsy and autopsy series of 93)			39
Nerve (in 20 autopsies)			14
Subcutaneous tissue			8
Pharynx ("rheumatoid granuloma") ...			1
Pituitary (degeneration of basophils) ...			1
Kidney (glomerulitis)			1
Salivary or lacrimal glands			2
Amyloidosis			7

which cannot be accounted for by intercurrent disease found at autopsy or mentioned in the clinical notes. Such lesions were found in 73 patients. Are these all systemic lesions of "rheumatoid arthritis"? "Rheumatoid granulomata" were found in the heart in 6 patients, in the spleen in a seventh and in the pharynx in an eighth. These lesions are frequently

regarded as specific, but similar nodules have been observed occasionally in patients who have not developed other stigmata of "rheumatoid arthritis" (Findlay, 1931; Klinge, 1933; Bergstrand, 1944; Cruickshank, 1952*a*). The lesions in the remaining 65 patients were certainly non-specific. It is not possible to discuss all the histological details in the present communication; the nature and interpretation of some of them have been discussed previously by Cruickshank (1952*a*, 1952*b*, 1954, 1957) and Sinclair and Cruickshank (1956). Thus it has been shown that there is good evidence for regarding much of the endocarditis, active or apparently healed, as being part of the "rheumatoid disease" rather than of an independent attack of rheumatic heart disease (Cruickshank, 1952*a*; Sinclair and Cruickshank, 1956). Evidence of the latter condition was seen in 4 patients; in another 2 patients healed valvular disease was present but microscopic sections were not studied. Most of the evidence that the cardiac lesions are rheumatoid, rather than rheumatic, is derived from histological studies. It is much more difficult to prove the relationship of the lesions in the myocardium and pericardium to the rheumatoid process; they frequently accompanied endocardial changes and were the sole cardiac lesion in only 6 cases, in 2 of which there was ample other evidence of systemic involvement. Most of the arterial lesions which occurred in these patients have been described and discussed by Cruickshank (1954). No "rheumatoid granulomata" were seen in the pleura. Aronoff *et al.* (1955) has argued that it is intellectually unsatisfactory to ascribe lesions for which there is no other obvious cause to the rheumatoid process. This may be so, but it is not surprising to find a high incidence of pleural involvement in this disease which may affect so many parts of the connective tissues. Indeed Aronoff *et al.* found pleural adhesions in 27 out of 42 autopsies in "rheumatoid disease" and in only 12 out of 42 controls. Baggenstoss and Rosenberg (1944) had previously found pleurisy in 22 out of 30 autopsies in "rheumatoid arthritis." Emerson (1956) has recently described pleural effusions in 6 patients with "rheumatoid arthritis" in whom no other cause could be demonstrated. It is unlikely that 42 out of 100 represents the true incidence of pleural involvement in "rheumatoid disease", for Sinclair and Cruickshank (1956) found pleural adhesions without apparent cause in 20 out of 90 controls. In the series now under review, the pleural adhesions were not associated with other systemic lesions known to occur in "rheumatoid arthritis" in 18 of the patients, so that a figure between 20 and 40% probably represents the occurrence of pleurisy as part of "rheumatoid disease". Involvement of the spleen and lymph nodes is generally accepted as a feature of "rheumatoid arthritis"; the lesions encountered in the lymph nodes in the present series have been described by Cruickshank (1957). Lymphorrhages in muscle and nerve are included in Table II for, although not specific (Clawson *et al.*, 1947; Sokoloff *et al.*, 1950), they occur more frequently, and are more numerous in "rheumatoid arthritis" than in other conditions (Cruickshank, 1952*b*) and are therefore probably part of the systemic disease. The low incidence of degeneration of pituitary basophils (Pearse, 1950, 1956) was due to the infrequency with which this gland was examined in the earlier autopsies and to the inadequate freshness of many of the later autopsies. The glomerulitis was similar to that encountered by Baggenstoss and Rosenberg (1943). The interpretation of amyloidosis as a systemic manifestation of "rheumatoid disease" was discussed by Sinclair and Cruickshank (1956). The relationship of these various visceral lesions to the activity of the joint lesions at the time of death is shown in Table III.

TABLE III.—INCIDENCE OF VISCERAL LESIONS IN RELATION TO ACTIVITY OF ARTHRITIS AT AUTOPSY

	Joint lesions active	Joint lesions inactive	Total
One organ or tissue involved	11	23	34
Two organs or tissues involved ...	7	13	20
Three or more organs or tissues involved	12	7	19
Visceral lesions active	20	13	33
Visceral lesions inactive	10	30	40
Total number of cases	30	43	73

It is important to note that widespread and active visceral lesions may occur in patients whose arthritis is no longer active. When the patients in whom myocarditis, pericarditis or pleurisy were the only visceral lesions are deducted from the total, there remain 52 patients with visceral lesions attributable to the rheumatoid process.

Considerable interest has been stimulated recently by the description of certain lung lesions in "rheumatoid arthritis". "Rheumatoid granulomata" have been described by Ravel *et al.* (1948), and several other authors. In view of the pleomorphic nature of the lesions of pulmonary tuberculosis, it is essential that this condition be excluded in all suspected examples of "rheumatoid granulomata" of the lung. Investigation of these lesions should include amino-acid analysis (Consden and Glynn, 1955); failure to demon-

strain tubercle bacilli by the Ziehl-Neelsen stain cannot be regarded as excluding tuberculosis, particularly when the granulomata are confined to the lungs and hilar lymph nodes (Skogrand, 1956) or are atypical (Christie, 1954, Case 1). Modified "rheumatoid granulomata" have been described in the lungs of patients with pneumoconiosis by Gough *et al.* (1955). Interstitial pneumonia has been observed by Ellman and Ball (1948) and several other authors. The relationship of interstitial pneumonia and diffuse interstitial pulmonary fibrosis to "rheumatoid disease" has been reviewed recently (Rubin, 1955). None of the several authors who have described this type of lesion has regarded it as specific. Recently Price and Skelton (1956) have described focal arteritis and bronchiolitis in one patient. Neither nodular lesions, nor the changes described by Price and Skelton were seen in this series. However, there were six examples of interstitial pneumonia. The lesions were all chronic and were accompanied by diffuse or focal fibrosis. Associated bronchiectasis was seen twice, causing honeycomb lungs in one patient. These lung lesions have not yet been studied in detail. The incidence of interstitial fibrosis in a series of 6,000 unselected autopsies reviewed by Mallory (1948) was 16. It thus seems likely that the association of interstitial pneumonia and fibrosis with "rheumatoid disease" is more than coincidental.

It is appreciated that many patients suffering from "rheumatoid arthritis" are not admitted to hospital and that few of those who die are examined by a pathologist. Nevertheless, this series includes a considerable number of patients whose arthritis was inactive on admission to hospital and remained so until death, which was due to an unrelated disease. Active visceral lesions were found in some of these patients. The clinical and pathological features in 16 of the patients with widespread visceral involvement has been discussed by Sinclair and Cruickshank (1956) who found that the visceral lesions, particularly those in the heart, were the main cause of death in 8 patients and a major contributing factor in another 7 patients. Surely it is more correct to regard these patients as suffering from "rheumatoid disease" (Ellman and Ball, 1948), than "rheumatoid arthritis", however convenient the latter may be as a clinical diagnosis. It must be emphasized that the term "rheumatoid disease" as used by Ellman and Ball and most subsequent authors is applied to patients in whom joint lesions were a cardinal feature at some stage in the disease. The patients reviewed here all presented with arthritis of the rheumatoid type. "Rheumatoid disease" in this sense is not to be confused with the "anarthritic rheumatoid disease" of Bagratuni (1956), the histological features of which have not yet been described. Although few, if any, of the systemic lesions are truly specific, the combination of joint and visceral lesions of "rheumatoid disease" give an overall pathological picture which has not been described in any other condition. "Rheumatoid disease" must, therefore, be considered a pathological entity rather than merely a clinical syndrome.

Dr. A. T. Richardson (Royal Free Hospital): *Routine Clinical Pathology in Rheumatoid Arthritis*

Rheumatoid arthritis, although usually defined as a non-suppurative polyarthritis of unknown ætiology, is now generally regarded as a systemic disease with widespread connective tissue involvement. Thus, its diagnosis is based not only on the character and distribution of the arthritis but also upon the co-existence of a constitutional disturbance, and on the results of one or more of a bewildering number of serological reactions. In this paper I would like to review the value of some of the laboratory investigations used routinely in the diagnosis and management of this disease. It is based on clinical experience with 332 cases referred to the Department of Physical Medicine and Rheumatology, Royal Free Hospital, during 1954 and 1955.

Without doubt the erythrocyte sedimentation rate (E.S.R.) is the most widely used investigation in the diagnosis of rheumatoid arthritis, it being generally accepted that it is raised during the active phase of the disease. Fig. 1 shows the first hour E.S.R.s (Westergren) in

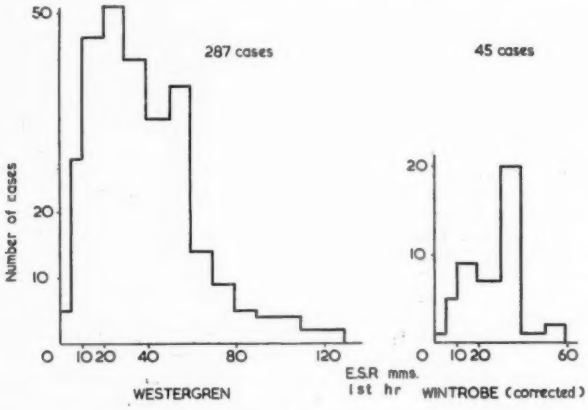

FIG. 1.—Erythrocyte sedimentation rates in rheumatoid arthritis at first attendance.

287 consecutive patients and first hour E.S.R.s (Wintrobe corrected) in 45 others at their first attendance. The cases with normal sedimentation rates (11·5% under 10 mm. in first hour in the Westergren series) were by no means entirely those with burnt-out disease attending for correction of residual deformities or for treatment of superadded degenerative joint changes, for 14 of these 33 had signs of active disease in non-weight-bearing joints and showed within one year of their attendance a raised E.S.R. of more than 35 mm. and progression of the disease. A further 2 cases had active and progressive disease for over two years with a persistently normal E.S.R.

Second only to the use of the sedimentation rate in this disease is the estimation of the hæmoglobin level. Fig. 2 shows the range of values in a series of 294 consecutive patients at first attendance, 75% showing values of over 80%.

However, the use of E.S.R. and hæmoglobin estimations in the diagnosis of rheumatoid arthritis is of greatest value at the stage of a prodromal constitutional disturbance, e.g., anorexia, excessive fatigue or transient muscle pains and stiffness, &c. Similarly it is of great value in the early diagnosis of the surprising number of cases labelled as metatarsalgia, capsulitis of the shoulder, tenosynovitis, bursitis, painful heel, &c., who subsequently develop a polyarthritis. In this connexion it is interesting that a large number of a series of patients with unexplained persistently raised E.S.R.s, followed by Ansell and Bywaters (1957) subsequently developed rheumatoid arthritis.

It is for such cases and indeed to define rheumatoid arthritis and its variants more accurately that a reliable and specific laboratory test is required. Of all the serological reactions investigated so far, the sheep cell agglutination test (D.A.T.) has proved to be the most specific. The technique that has been used is the modification described by Ziff and his colleagues (1954), the so-called euglobulin agglutination test. They claimed 92% of positive results in 82 cases of rheumatoid arthritis as opposed to 78% using whole serum and a reduction in the number of false positives. In contrast, Bernstock, Bedson and Glynn (1956) reported disappointing results with this technique although they confirmed the low

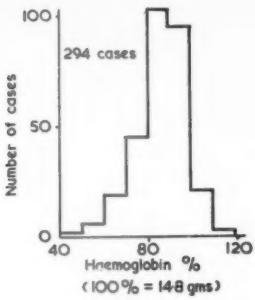

FIG. 2. — Hæmoglobin levels in rheumatoid arthritis at first attendance.

rate (2%) of false positives. The first 300 patients tested by Dr. E. Hess, who has carried out this work in my Department, included 130 with rheumatoid arthritis of which 110, or 85% gave a positive result at titre of 1/64 (Table I), of these, 22 had a history of under six months.

TABLE I.—RESULTS OF EUGLOBULIN ROSE'S TEST

Disease	Total cases	Number positive
Rheumatoid arthritis	130	110
Rheumatoid variants	3	3
Rheumatoid arthritis with psoriasis ...	5	—
Dermatomyositis, neuromyositis and polymyositis	5	2
Systemic lupus erythematosus	9	6
Osteoarthritis	44	1
Gout	6	—
"Menopausal" arthritis	15	1
Specific arthritides	4	—
Rheumatic fever	3	—
Ankylosing spondylitis	12	—
Normal controls and other diseases ...	64	—

The 20 negative cases included 6 with titres of 1/32. Of the remaining 14 rheumatoids with negative results, 4 had histories of under six months and 3 had inactive disease. 9 cases of rheumatoid arthritis with a positive euglobulin test but an initially normal E.S.R. have occurred and we have one case of tenosynovitis with a normal E.S.R. and positive euglobulin test who subsequently developed rheumatoid arthritis. Positive results have also been obtained in systemic lupus erythematosus and some members of the polymyositis syndrome. In the other arthritides, such rheumatoid variants as Reiter's, Sjögren's and Still's disease have shown positive results. In contrast, psoriatic arthritis has given consistently negative results and indeed a negative Rose's test has become accepted as one of the criteria for this diagnosis (Wright, 1956). Of considerable interest also is the fact that the so-called mixed or menopausal arthritis (a distinct clinical entity) rarely shows a positive Rose's test. Similarly, patients with ankylosing spondylitis give a negative Rose's test as do an array of other diseases.

Serological investigations, no matter how complete, do not entirely eliminate the need for joint biopsy and for examination of the synovial fluid for organisms; in particular it is in cases with an insidious onset of pain and swelling of a single large joint that such investigations are required. In my series no less than 36% had a large joint onset, it occurring most commonly in men and sometimes in a single joint whose fluid could not be obtained, an occurrence peculiarly suggestive of tuberculous infection and needing biopsy. In fact, no case of a tuberculous joint occurred during the period surveyed in this review; the only specific types found were 2 following Neisserian infection, 1 following meningococcal infection and 1 following staphylococcal infection in a patient on cortisone.

The indication for biopsy in the diagnosis of rheumatoid arthritis is, however, not confined to joints; in particular it has a place in the differential diagnosis of tenosynovitis. Thus while it is well-known that nodular tendonitis and tenosynovitis may co-exist with rheumatoid polyarthritis, that these lesions may precede joint involvement is not so widely appreciated. In my series the onset was in the tendon sheaths in 7, and in 3 cases, reported elsewhere by Jacobs, Hess and Beswick (1957), tenosynovitis, whose rheumatoid origin was indicated by biopsy, preceded the polyarthritis respectively by four, fourteen and eighteen months, 2

cases having a normal E.S.R. during that time although one had a positive differential agglutination test.

The prognosis of rheumatoid arthritis is, of course, notoriously unpredictable both clinically and in terms of pathological findings. Most of the work on this has been done on patients admitted to hospital, the most recent series being that of Duthie and his colleagues (1955) whose conclusion was that a high E.S.R. in the early stages carries a relatively good prognosis, but in the late stages a bad one. There are, however, many contradictions to this rule.

In an endeavour to illustrate the place of the E.S.R. in prognosis I have taken from the records 39 of the functionally most mildly affected cases and 33 very severely affected ones, in fact rheumatoid cripples, as judged at three years from their first attendance. The state of their E.S.R.s and hæmoglobins at first attendance compared with the total series showed no significant deviation at the ·05 level (Table II). The most significant finding was a low

TABLE II.—RESULTS AT FIRST ATTENDANCE

	E.S.R.s mm. First hour (Westergren)		Hæmoglobin %	
	Mean and S.E. of mean		Mean and S.E. of mean	
Total Patients ...	(287)	36·5 ± 1·4	(294)	85·8 ± 0·7
Mildly affected ...	(39)	44·0 ± 4·5	(39)	87·8 ± 2·2
Severely affected ...	(33)	42·1 ± 4·6	(33)	81·8 ± 2·4
Steroids used ...	(28)	38·8 ± 5·5	(22)	86·7 ± 3·3

hæmoglobin in the severely affected and a high E.S.R. in the mildly affected. As another index I have taken 28 cases who ultimately required long-term steroid therapy. As, in general, the indication for this was progressive systemic illness in spite of prolonged hospitalization, it is perhaps more an index of systemic disease than are functional studies. However, again the level of the E.S.R.s and hæmoglobins at first attendance compared with all groups showed no significant variation.

Study of the trends in these E.S.R.s and hæmoglobins over three years again showed no marked changes although 4 cases who showed a very high initial E.S.R. (80–100 mm. first hour) which dropped after hospital admission retained good function for three years. These are, of course, examples of patients whose rheumatoid arthritis was of explosive onset, but in whom hospitalization brought about a rapid remission and who, therefore, on clinical grounds alone would be regarded as having a relatively good prognosis. The most significant difference between those severely and those mildly affected was the duration of the illness before they first attended, the mean of the former being 8·3 years and of the latter, 4·1 years.

Any discussion on the place of routine clinical pathology in the diagnosis and prognosis of rheumatoid arthritis would be incomplete without some reference to the occurrence of widespread extra-articular connective tissue changes in this disease. The common occurrence of these has encouraged some to recommend the use of the term "rheumatoid disease" in place of "rheumatoid arthritis". Certainly in clinical usage "rheumatoid disease" or "soft tissue rheumatoid" is being increasingly applied where it is not the polyarthritis but the co-existing vascular, muscle or other soft tissue lesions or even the general constitutional disturbance which dominate the clinical picture but where pathognomonic clinical signs and the absence of L.E. cells, &c., do not indicate an alternative diagnosis, although the progress of the patient may well do so. Diagnosis in these circumstances is, however, difficult, for while members of their so-called connective tissue group of diseases possess a common pattern of pathological change, they exhibit a wide variety of clinical manifestations very few of which are pathognomonic and many of which are common to all.

My experience is based on 8 cases additional to the series of 332 cases who presented as polyarthritis but whose subsequent progress demanded a revision of the initial diagnoses: 7 into systemic lupus erythematosus and 1 into progressive systemic sclerosis. In 5 of these cases the true diagnosis was reached on clinical grounds alone, but in 2 the behaviour of the E.S.R. was largely responsible.

The patient with systemic sclerosis presented with a polyarthritis which was accompanied by severe Raynaud's phenomenon, an E.S.R. of 107 mm. and a hæmoglobin of 79%. In hospital the E.S.R. maintained a high level and she developed marked proximal muscle wasting. Electromyograms and biopsy showed the changes of polymyositis which was accompanied by twenty-four-hour urine creatine of 680 mg. She subsequently and while on cortisone developed sclerodermatous changes in the skin.

A further case presenting with a rheumatoid type of polyarthritis, was admitted because of severe constitutional disturbance although his E.S.R. at first attendance was only 10 mm. This E.S.R. rose steadily during the first three months in hospital to 65 mm. when he developed a chest lesion characterized by patchy consolidation of one base, fever, a white cell count consistently below 4,000, negative sputum examination and bronchoscopy. While L.E. cells have not been found at any time he has now developed the typical L.E. rash over the dorsum of the hands.

In contrast, reference must be made to the persistently low E.S.R. found sometimes in the type of case we are now recognizing more often, in which a patient with a long-standing rheumatoid type of polyarthritis develops clinical signs of systemic lupus erythematosus.

One such patient of mine with a low-grade polyarthritis of nine years' standing and intermittent leg ulceration developed a pleural effusion at which time L.E. cells were found. She subsequently developed a typical rash on the palm of one hand but throughout her illness to date her E.S.R. has not exceeded 30 mm. She has shown no signs of renal involvement and she is in fact very well. There can be no doubt of the diagnosis of this patient who supplies evidence that lupus erythematosus as defined by the presence of L.E. cell phenomenon and by the classical clinical signs can be a chronic illness with a far better prognosis than formerly implied by this diagnosis.

In conclusion, therefore, it would seem that the E.S.R. and to a lesser extent, the hæmoglobin level have a real place in the diagnosis of rheumatoid arthritis. They are, however, a poor index of the prognosis of joint function and of the presence of accompanying systemic changes which are important in that they may lead to revision of the diagnosis, although perhaps not always the prognosis. To these routine investigations has now been added Rose's test, which because of its relative specificity has, I believe, a useful place in the diagnosis of this disease. Indeed, it is to tests of this sort and the L.E. cell phenomenon that we must turn to sort out the semantic confusion that surrounds the diagnosis of this group of disorders—a confusion to which clinical use of the term "rheumatoid disease" may well add unless it is clearly defined or perhaps allowed to replace the term "rheumatoid arthritis" entirely, thus ignoring the characteristic lesion in the vast majority of cases.

Waaler in 1940 and Rose *et al.*, in 1948, independently reported that in the majority of patients with rheumatoid arthritis the serum contained a factor that potentiated the agglutination of sheep cells previously coated with a sub-agglutinating-dose of rabbit anti-sheep serum. By various refinements the test has been improved so that it has been claimed to give a positive reaction in over 90% of cases. It is, therefore, of great interest to determine the nature of the serum factor responsible.

A consideration of the literature on modifications of the test, which is shown in an abstracted form in Tables I and II, leads to the conclusion that a positive result, independent

of the method used, depends upon the interaction of the Rose-Waaler factor with a γ-globulin. The simplest explanation of the observed facts, however, is that the globulin with which the factor reacts is in some way altered. In view of the observation that the γ-globulin involved can be obtained from any of several different species the interaction must be regarded as occurring between the factor and non-specific groupings common to the γ-globulins of many species. Since, in the majority of the tests, the γ-globulin is pre-combined with some specific antigen, it suggests that these non-specific groupings are exposed as a result of unfolding of the coiled γ-globulin consequent upon its interaction with specific antigen. This unfolding is shown diagrammatically in Fig. 1.

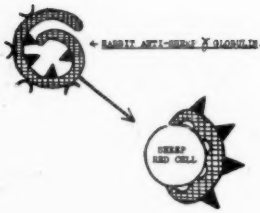

FIG. 1.—Diagram showing the coiled state of the free antibody molecule and the manner in which it is postulated that it uncoils when it reacts with its specific antigen.

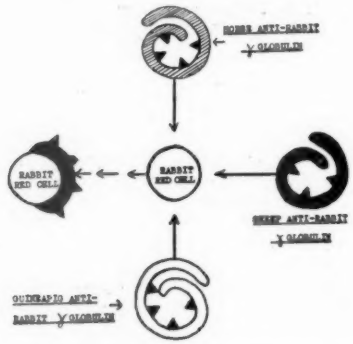

FIG. 2.—Diagram of hypothetical antibody molecules from four different species to show how common non-specific groups could be exposed as a result of the interaction of the antibody with the antigen.
